New York.

LIST OF CONTRIBUTORS TO VOL. XXXI.

Abbe, Dr. Robert, New York.
Abbott, Dr. George E., New York.
Alderson, Dr. M. E., Russellville, Ky.
Allen, Dr. Charles W., New York.
Allen, Dr. H. N., Seoul, Corea.
Amidon, Dr. R. W., New York.
Atkins, Francis H., Esq., Las Vegas, N. M.

Bailey, Dr. James L., New York.
Baldy, Dr. J. M., Philadelphia, Pa.
Bangs, Dr. L. Bolton, New York.
Barber, Dr. C. F., Brooklyn, N. Y.
Bartlett, Dr. Edwin J., Hanover, N. H.
Baruch, Dr. Simon, New York.
Beaver, Dr. Daniel D. B., Reading, Pa.
Belfield, Dr. William T., Chicago, Ill.
Bennett, Dr. W. H., Brooklyn, N. Y.
Billington, Dr. C. E., New York.
Blackstone, Dr. William B., Hebron, Ind.
Blaine, Dr. M. D., Ovid, N. Y.
Bodenhamer, Dr. William, New York.
Bogle, Dr. John C., Danville, Ky.
Bosworth, Dr. F. H., New York.
Boyd, Dr. B. H., La Fayette, Ind.
Brandt, Dr. J. R., Chicago, Ill.
Bridgwater, Dr. S. C., Dixon Springs, Tenn.
Brothers, Dr. A., New York.
Brown, Dr. Daniel, New York.
Brown, Dr. Dillon, New York.
Brown, Dr. S. A., Sioux Falls, Dak.
Browning, Dr. William, Brooklyn, N. Y.
Brush, Dr. E. F., Mount Vernon, N. Y.
Buck, Dr. Albert H., New York.
Bundy, Dr. A. D., St. Ansar, La.
Burdett, Henry C., Esq., London, Eng.
Buxton, Dr. Dudley, London, Eng.

Caillé, Dr. A., New York.
Carhart, Dr. J. W., Lampasas, Tex.
Carpenter, Dr. James S., Pottsville, Pa.
Carpenter, Dr. Wesley M., New York.
Carr, Dr. Walter Lester, New York.
Cassidy, Dr. J. J., Toronto, Ont.
Cauldwell, Dr. Charles M. New York.
Chapin, Dr. Amory, New York.
Chapin, Dr. Henry Dwight, N. Y.
Cheesman, Dr. William S., Auburn, N. Y.
Chew, Dr. S. C., Baltimore, Md.
Coan, Dr. Titus Munson, New York.
Collins, Dr. J. W., Toronto, Ont.
Copeland, Dr. W. P., Eufala, Ala.
Corning, Dr. J. Leonard, New York.
Curtis, Dr H. Holbrook, New York.
Curtiss, Dr Romaine J., Joliet, Ill.

Dabney, Dr. William C., University of Virginia.
Dana, Dr. C. L., New York.
DeGarmo, Dr. W. B., New York.
Delafield, Dr Francis, New York.
Delavan, Dr. D. Bryson, New York.
Dellenbaugh, Dr. Z. T., Cleveland, O.
Denhard, Dr. Charles E., New York.
Duhring, Dr. Louis A., Philadelphia, Pa.

Ecroyd, Dr. Henry, Jr., Newport, R. I.
Edgar, Dr. J. Clifton, New York.
Edson, Dr. Benjamin, Brooklyn, N. Y.

Einhorn, Dr. Max, New York.
Elliot, Dr. George T., New York.
Elliott, Dr. George R., New York.
Ellis, Dr. H. L., Brooklyn, N. Y.
Emmet, Dr. Thomas Addis, New York.

Finley, Dr. Mary J., Mansfield, O.
Fisher, Dr. W. C., Galveston, Tex.
Flood, Dr. Henry, Elmira, N. Y.
Fruitnight, Dr. J. Henry, New York.
Fuchs, Dr. Albert F., Fredonia, Wis.

CHRONIC CATARRHAL INFLAMMATION OF THE MIDDLE EAR.[1]

BY ALBERT H. BUCK, M.D.,

NEW YORK.

GENTLEMEN: Chronic catarrhal inflammation of the middle ear is a trite theme, and one that I have great hesitation in writing upon, for fear that when I have said all that I may have to say, you will accuse me of wasting your time with matters already perfectly familiar to you. I certainly cannot hope to throw any new light on this old subject; but, while making this confession, I am disposed to look upon the merchant's practice of periodically taking account of stock as one that we medical men may sometimes adopt to advantage. I propose, therefore, to-night to take some account of our stock of knowledge in regard to this exceedingly common aural affection, in the hope that I may succeed, here and there, in drawing your attention to points about which you have perhaps forgotten, or the value of which you may have underrated. The stand-point from which I shall judge the value or lack of value of these points will necessarily be that of my daily experience in practice. Therefore, in what I may commend and in what I may condemn, you will know that I am simply expressing personal views, which may or may not be in accord with those which are commonly accepted. I have neither the time nor the taste to wade through all the literature of the subject and present to you an impartial, and, therefore, almost necessarily colorless, *résumé* of the views held by different authorities in regard to the etiology, pathology, and therapeutics of chronic catarrhal inflammation of the middle ear. The teachings of these men have, at some time or other, exerted their legitimate influence in building up and modifying my own views. Hence, in large measure, I am justified in speaking, as I have already done, of *our* stock of knowledge. Let us overhaul this stock and see what our possessions are to-day, and how they compare with what we possessed a few years ago.

First, with regard to the nature and characteristics of the affection. What are our conceptions to-day in regard to it, and are they any more clearly defined than they were fifteen years ago? Are we still obliged to apply the expression "chronic catarrhal inflammation of the middle ear" to pathological processes and conditions many of which are doubtless of an entirely different nature? Has a further acquaintance with the course of the disease enabled us to predict, any more accurately than before, what is likely, in any given case, to be the issue as regards both the hearing power and the persistence of some of the concomitant subjective symptoms? These questions, I fear, cannot be answered any more precisely to-day than they could fifteen years ago. Local conditions or lesions of the middle ear, entirely independent of anything worthy the name of catarrhal disease, are doubtless at times still mistaken by all of us for the latter affection. And how could it be otherwise? Are we likely ever to discover means for rendering an intact drum membrane so transparent that we may interpret correctly pathological lesions of the middle ear, which now are known to us only through post-mortem studies? And, again, if it were even possible to temporarily remove the drum membrane, should we be able to obtain a view of those vital parts of the auditory mechanism which lie outside of the range of vision of a person looking into the external auditory canal from without? I think not; and yet, despite all the difficulties which beset the study of this class of diseases, I believe that those who are reasonably familiar with affections of the ear do not often mistake other pathological middle-ear conditions or processes for that which is now under consideration.

I shall not attempt to paint the picture of a disease one of the chief characteristics of which is its almost entire lack of salient features. You are all thoroughly familiar with its symptomatology, and I may, therefore, dismiss this part of the subject from further consideration. Our conceptions of the pathology of the disease are also probably the same. There is one respect, however, in which I am disposed to believe that the views held to-day are appreciably in advance of those held twenty years ago. I refer to the relative importance assigned to the two seats of the catarrhal disease, viz., the Eustachian tube and middle ear on the one hand, and the vault of the pharynx on the other. At the earlier date almost the entire force of our therapeutic energies was concentrated upon the Eustachian tube and middle ear, while the vastly larger tract of mucous membrane at the vault of the pharynx received comparatively little attention. And yet, even among the earlier authorities, there were some—Von Troeltsch, for example—who laid stress upon this point. Nevertheless, I believe that I am correct in the statement that it was not a general belief. At the present time there are few, I imagine, who do not look upon the pharyngeal centre of the disease as by far the more important of the two, and that unless we can successfully treat the larger area it is comparatively useless to bring therapeutic agents to bear upon the smaller one. Personally, I am disposed to state the case even more strongly. I believe that in a very large proportion of the cases treatment directed to the vault of the pharynx is all that is required in the way of local interference; or, to put the statement in somewhat different terms, that the application of remedies to the vault of the pharynx *alone* will, in a large proportion of cases, effect a greater amount of improvement in the condition of the middle ear and Eustachian tube than can be effected by applications made directly to these parts.

We come, next, to the consideration of the causes of this disease. How stands our knowledge with regard to these? Have we made any progress during recent years in fathoming this mystery? So far as the intrinsic causes are concerned, we still possess only very few, and these often contradictory, facts. In some cases the tendency to catarrhal inflammation of the pharyngeal and neighboring mucous membranes appears to have been handed down from parents to children, and we speak of the disease as having been inherited. Just as often, however, do we fail to trace the origin of the disease to any such influence. If our knowledge of the direct causes, however, is no more precise now than it was years ago, we have, I believe, gained clearer conceptions of the factors which promote a continuance and an undue activity of the catarrhal process. Not only do we appreciate thoroughly how cold may disturb the delicate balance maintained between the functional activity of the skin and the state

[1] Read before the Ophthalmological and Otological Section of the Academy of Medicine, December 20, 1886.

of the blood-vessels and glandular structures of the pharyngeal mucous membrane, but we have learned that a similar interdependence exists between the condition of the latter region and the activity of the metabolic processes (those of assimilation and destructive metamorphosis). In other words, we have learned, in recent years, to recognize the gouty or lithæmic throat as a well-defined type of catarrhal disease. The importance of this discovery will appear when we take up the question of therapeutics for consideration.

To the clinical observations and therapeutic studies of the past ten years we owe the very valuable discovery that obstruction of one nasal passage — when associated, as it sometimes, or, perhaps, often is, with hypertrophy of the mucous membrane of the vault of the pharynx in the median line — produces very much the same mechanical effects upon the drum cavity of the corresponding side, and upon its contents, as does an obstructed Eustachian tube. The mechanism of the action, however, is different. Each act of swallowing means the exhaustion of the air in the vault of the pharynx. In a normal condition of the nasal passages air enters freely through these to fill the vacuum created by the swallowing. The aërostatic conditions in the drum-cavity are therefore very little, or not at all, disturbed by this act. But let the nasal and naso-pharyngeal obstructions occupy such positions that air cannot instantly rush in from the nasal cavities to fill the vacuum referred to, a suction force will immediately be exerted upon the air contained in the tympanic system of cavities. The result is of a twofold character: there will be, for a short time, greatly diminished atmospheric pressure upon the mucous membrane of the middle ear on the one hand, and greatly increased atmospheric pressure upon the outer surface of the membrana tympani on the other. Imagine this state of things to be repeated scores of times every day, and it will be an easy matter to understand how injurious the effects may be upon the apparatus of hearing.

Among the minor exciting causes, the influence of which in aggravating and perpetuating the catarrhal activity is better understood to-day than it was in former years, may be mentioned tobacco-smoking. The habitual practice of forcing the smoke from the mouth into the naso-pharyngeal cavity and thence out through the nasal passages, is highly conducive to the maintenance of a congested and swollen naso-pharyngeal mucous membrane. It is not improbable that the smoke of burning paper, as where cigarettes are used, is more irritating to the parts than is that of the tobacco-plant alone. But even the mere smoking of a cigar or pipe in the ordinary manner aggravates the catarrhal irritation. The smoke is drawn into the cavity of the mouth, and is then almost immediately expelled. While it would seem as if this mode of using tobacco ought not to bring any of the smoke in contact with the pharyngeal and naso-pharyngeal mucous membrane, it is a well-established fact that the smoke does constantly come in contact with these parts and exerts upon them a drying, and therefore an irritating, effect.

Climatic influences have always been considered as active agents in promoting or restraining chronic catarrhal inflammation of the middle ear; but I am not aware that we have yet learned how to differentiate between the conditions of soil, atmosphere, rainfall, wind, etc., which promote the catarrhal activity and those which favor its subsidence. The prevailing belief that dampness of the soil and of the atmosphere, and also that high winds and dust favor catarrhal disease, is undoubtedly in the main correct; but we so often encounter exceptions to this rule that we are obliged to confess that our knowledge is not yet equal to the task of defining the climatic conditions that favor catarrh.

In former years it was a very common practice to use both woollen and fur wraps about the throat during the winter season. This practice has now very greatly diminished, and I am disposed to believe that the diminution may in large measure be ascribed to the protests of sensible medical men. However appropriate such wraps may be in more northerly latitudes, it is very certain that in a climate like that of New York, woollen mufflers and fur collars are harmful rather than beneficial; they play an active part in promoting catarrhal affections of the throat and nose.

There is still another way in which the catarrhal tendency of certain individuals is kept active during the cold season. I refer to the peculiarly American craze for fresh air under any and all circumstances. Sometimes the fault lies with the sufferer himself or herself, and manifests itself in the adoption of the habit of always sleeping in a room with an open window. Sometimes, however, the sufferer is perfectly innocent, but falls a victim to the selfishness of one of those fresh-air fiends who make our railway cars, our club-rooms, and other places of public assembling, nurseries of pneumonia, bronchitis, and countless minor ailments.

Finally, there is another exciting cause, which I believe is much more common than it is generally supposed to be. I refer to the irritating effects of retained and inspissated secretion in the crypts of the tonsils. In former years I saw but few of these cases, as it was not my habit to explore these cavities unless I saw actual evidence, in the shape of a whitish spot, showing that there was such an accumulation in the crypt. In recent years I have adopted the rule of exploring the half-dozen or more crypts in each tonsil whenever I find them appreciably enlarged, and especially if they show decided evidences of congestion. A slender ring-shaped curette of steel, with nicely rounded edges, answers the purpose of an exploring and evacuating instrument admirably. The improvement which follows the removal of these foul-smelling cheesy masses, and the washing out of the cavities with a moderately strong mixture of Listerine[1] and water (1 to 3 or 4) is generally very pronounced.

We come now to the consideration of the treatment of the disease. As you are well aware, a large proportion of the cases which come under our observation may be classed as incurable. My impression is that they are incurable, as a general thing, because the catarrhal changes have reached the last stage, that of contraction and atrophy of the previously swollen mucous membrane. It is safe to assume that, as a result of these changes, there is diminished mobility of the joints of the ossicles, and particularly of the stapedio-vestibular joint or of the membrane which holds the stirrup firmly in the oval window. But in a good many cases which seek aid from the physician the disease is still in the stage of congestion, hypertrophy and hypersecretion, and under these circumstances we may reasonably expect to obtain beneficial results from the adoption of suitable therapeutic measures. The first thing to be done, in every case, is to examine carefully into the antecedent history and habits of life. By such an examination we shall often be able to determine whether we are dealing with a catarrh which is aggravated by tobacco-smoking; or with one which is kept unnecessarily active by exposure of the uncovered head to slight draughts of cold air during sleep; or, finally, with one which owes its chief activity to a lithæmic diathesis. In the case of the smoker it may not be necessary to interdict the practice altogether; an indulgence in a single cigar, or at most two, during the twenty-four hours, will often be found permissible. On the other hand, the practice of sleeping, in cold weather, with the window of the room partially opened, should be abandoned. I have known a distressing tinnitus aurium to disappear soon after the sufferer had abandoned this practice; and at a later date, when the same person again allowed the window to remain open a distance of a few inches, at night, the tinnitus at once reappeared, to disappear again when the practice was for the second time abandoned.

[1] Listerine is a manufactured fluid preparation containing, among other ingredients, thymol.

A chronic naso-pharyngeal catarrh, in a person suffering from lithæmia, is an exceedingly stubborn affection to treat. Local applications alone seem to make very little impression upon the swollen mucous membrane. In former years, before I appreciated how important a part this lithæmic condition played in the causation, or at least aggravation of these chronic catarrhs, I used to wonder at the insignificance of the results obtained by my systematic paintings of the pharynx with nitrate of silver solutions. At the present time I can see how irrational such treatment was. It dealt with a mere surface manifestation of the disease, while ignoring the chief underlying cause.

The proper way of managing these cases is to aim first at securing the complete elimination from the circulation, and from the tissues generally, of the offending materials. Inquire minutely into the patient's daily life, as regards the amount of physical exercise which he is in the habit of taking, and also as regards his diet (both food and drink). Almost invariably it will be found that the patient takes far less exercise, especially outdoor exercise, than is essential to the proper elimination of the waste materials of the body. Insist upon it—in the case of a full-grown man—that he shall get, on an average, not less than four miles of walking daily, or the equivalent of this in some other form of open-air exercise. In the matter of diet, he should be urged to leave off coffee, pastry, and all alcoholic drinks—or else to add an extra mile or two of walking as an offset to these indulgences. A warm bath every night, followed by brisk rubbing with a coarse towel, will stimulate the skin to perform its emunctory functions with increased vigor. Every morning, or every other morning, on rising, and at least half an hour before breakfast time, he should take a heaping teaspoonful of Rochelle salts dissolved in a tumblerful of water. This will serve the double purpose of facilitating elimination by way of the kidneys, and of stimulating the bowels to greater activity. A glass or two of Vichy water, taken during the course of the day, between meals, will serve as an additional aid in facilitating the process of elimination.

There are not a few patients, generally men of portly habit and well-to-do in the world, who seem to lack the energy necessary for the faithful carrying out of these instructions in regard to exercise, etc. They are so stereotyped in their daily business habits that they resent any advice that calls for the slightest disturbance of these habits. Such patients often find it easier to give up their business altogether for two or three months; and when this is the case I urge them to go abroad, and spend a month or six weeks at Carlsbad, Aachen, Baden-Baden, or at any other well-organized bathing establishment, where the systematized drinking of the waters, under competent medical guidance, together with a simple diet, regular hours of retiring, and quiet outdoor life, exerts a markedly beneficial effect upon the lithæmic condition in general, and upon the local pharyngeal condition in particular. It seems strange that in our own country we should still lack similarly well-organized bathing establishments. There certainly is no lack of suitable medicinal springs, but, unless I am inadequately informed on the subject, there is not a single bathing institution in the country where we can send a patient with the same degree of confidence as we can to Carlsbad, Aachen, or a dozen other places that I might name.

In a few cases, as, for example, those of women with uterine affections, and of men with rheumatic or gouty affections of the lower limbs, we cannot secure the desired amount of voluntary physical exercise, and we are consequently compelled to fall back upon the less valuable methods of passive exercise—massage, the so-called parlor gymnastics, etc. While these means are not so effective as good outdoor exercise (walking, riding, rowing, tennis, etc.), they can nevertheless be relied upon, if carried out faithfully and intelligently, to accomplish the same results in the course of a longer period of time.

Finally, we come to the consideration of the local treatment of the disease. As I stated in an earlier part of this paper, the chief object aimed at, from fifteen to twenty years ago, was to bring remedies to bear directly upon the tympanic cavity proper. The lesions affecting the apparatus of hearing are, it was argued, chiefly located in this cavity, and the inference was therefore drawn that the remedies which are suitable for the relief of these lesions should be brought to bear directly upon them. From this idea developed the practice of forcing remedial vapors, sprays, and fluids into the middle ear through the assistance of the Eustachian catheter. While this method of treating the tympanic cavity was very generally employed by aural surgeons throughout the world up to about ten years ago—and is, so far as I can learn, still universally employed throughout continental Europe—in our own country it is used rather as a collateral aid; the doctrine being generally accepted that the main seat of the disease is located in the naso-pharyngeal cavity, and that our *chief* therapeutic efforts must be directed to this region if we wish to obtain a full measure of success. When we come, however, to compare the different procedures which the various authorities recommend as best suited for the attainment of the end desired, we find that there is a very wide divergence of opinions in regard to what are the best means of effecting a cure. Of all the different methods of applying remedies to this region, the favorite one at the present time, and for a long time past, is that by means of finely subdivided sprays. The use of the posterior nares syringe comes next, I think, in popularity. Curved instruments, armed with cotton which is to be saturated with the remedy selected, are, I suspect, not so generally preferred as are the other two methods; and yet my own judgment, based entirely on personal experience, promptly gives the preference—so far as both safety and efficiency are concerned—to the latter method. As I cannot claim that I obtain better results from treatment than do my colleagues who use the other methods of applying remedies to this region, it seems plain that there is no such thing as *the best* method. The old saying, "All roads lead to Rome," does not need to be greatly modified in order to make it apply to the subject in hand. There are certainly very many ways of making effective remedial applications to the vault of the pharynx.

The same diversity of opinions which exists in regard to methods is encountered when we come to consider the question of remedies. Nitrate of silver, tincture of iodine, tannin, alum, chloride of iron, carbolic acid, and a series of less important drugs, all possess strong advocates. Nitrate of silver and tincture of iodine are unquestionably the most efficient remedies known, in respect to their power to diminish undue vascularity, infiltration, and hypersecretion of a highly glandular mucous membrane. They are, however, difficult remedies to manage. Like a two-edged sword, they sometimes cut both ways—toward remedying the disease and toward aggravating it. This peculiarty of nitrate of silver, in particular, has led some excellent authorities to pronounce judgment in strong terms against the employment of this drug in the treatment of naso-pharyngeal catarrh. Such anathemas remind me of those which were pronounced, not many years ago, against the use of probes, steel hooks, forceps, etc., in the external auditory canal and cavity of the tympanum. Those who do not possess manual skill, and who are too lazy or too heedless to give careful thought to the different steps of any therapeutic procedure which they may adopt, should carefully abstain from the use of any instrument or drug that calls for both manual skill and judgment in its management. The mere fact, however, that a very valuable drug or remedial procedure is dangerous or inefficient when handled carelessly or without knowledge, should not warrant us in condemning it. We should rather aim at studying more thoroughly the conditions under which it may be used both safely and effectively.

I should only weary you, were I to enter into a detailed account of the different ways of using nitrate of silver or tincture of iodine both safely and efficiently, and I shall therefore pass on at once to the consideration of other matters.[1]

Hitherto, in discussing the question of treatment, I have referred only to those measures which are intended to relieve a diseased condition of the mucous membrane. Although these measures are of paramount importance, we cannot ignore the fact that we have also to deal with the mechanical effects resulting from this diseased condition. These effects are: First, increased atmospheric pressure upon the outer surface of the drum membrane, from obstruction of the Eustachian tube; and, second, the tendency of all fibrous tissues to contract or retract after long-continued inflammation. The tendons of the tensor tympani and stapedius muscles and the fibrous tissues of the ligamentum annulare (in the oval window), and probably, also, of the membrana tympani secundaria (in the round window), are the more important tissues which may undergo this change—a change disastrous to the function of hearing. As regards our ability to combat directly the two different conditions enumerated above, we stand to-day precisely where we stood twenty or more years ago. Inflations of the tube and middle ear constitute, practically, our only remedy for the relief of these conditions.

A word or two with regard to the home use of nasal sprays, and I will bring this unduly long paper to a close. Some months ago, at the suggestion of my friend Dr. Delavan, of this city, I instructed one of my patients—who has been for years a sufferer from chronic nasopharyngeal catarrh, accompanied by very distressing tinnitus which interfered seriously with sleep—to employ, several times daily, a nasal spray of one part of Listerine in three of water. The experiment proved quite successful, the relief of the tinnitus being very marked. I have, since that time, had occasion to recommend the same plan of procedure to several other patients, and the results obtained justify me in saying that it is at least worthy of being fairly tried in our treatment of this exceedingly rebellious form of disease. My impression is that the rapid decomposition which takes place in the nasal mucus that tarries in the various recesses of the vault of the pharynx, and in the adjoining nasal passages, lends to this secretion an irritating property, and that the Listerine spray, when used somewhat frequently, is competent to render it bland and unirritating. Valuable as this procedure may prove as an aid to the more fundamental methods already referred to, I do not anticipate that it will ever render these unnecessary.

Within the narrow limits of a single paper it is not possible to do justice to all the important questions which arise in connection with the topic which I have chosen. I have, therefore, made no attempt to cover the ground thoroughly, but have contented myself with discussing briefly such parts of the subject as I thought might prove of interest to you. In this way it happens that not a few points, some of them even of the highest importance, have not even been mentioned by me.

Tin Oleate for the Nails.—Thomas H. Irquhart writes to the *Therapeutic Gazette*: "I used the tin oleate some months ago on my finger-nails, which commenced to split and break soon after I left the army, the result of scurvy contracted in the military service. I anointed the nails every day with the oleate, and at night applied it on a narrow flannel bandage. In about two months all the nails were sound and tough. I applied the oleate to the nails of a young lady friend with like success. It is also a beautiful polish for the nails."

[1] Those who may not be familiar with these methods will find the matter discussed somewhat fully in my work on Diagnosis and Treatment of Ear Diseases, and under the heading "Ear: General Therapeutics," in the Reference Handbook of the Medical Sciences.

THE INFLUENCE OF MATERNAL IMPRESSIONS IN THE ETIOLOGY OF CONGENITAL DEFORMITIES.[1]

By THOMAS L. STEDMAN, M.D.,

late attending surgeon to the new york orthopædic dispensary.

Mr. Chairman and Members of the Orthopædic Section: It is with some misgivings that I have ventured to present this subject for your consideration this evening, for it is one that is generally classed with old wives' fables and popular superstitions, and regarded as unworthy of even passing attention from scientific physicians of the present sceptical age. However, I think you will all be ready to admit that our knowledge of the etiology of congenital deformities is as yet so rudimentary that we can ill afford to despise any effort made to solve the mystery, and it behooves us to examine, with at least respectful consideration, any theory, however contrary to our preconceived notions, which bears upon it the stamp of even slight plausibility. And I hope, as far as is possible in a brief paper, to demonstrate to you this evening that there are certain elements of plausibility in the assumption that the development of the fœtus in utero may be influenced for weal or for woe by the mental processes of the mother.

My attention was first directed to this subject when I was a student of medicine in Philadelphia in 1874. The late Professor Ellerslie Wallace, of the Jefferson Medical College, who was a firm disbeliever in the influence of maternal impressions, but who was a man who never shrank from facts which seemingly argued in the face of his theories, exhibited to the class the dead body of a full-term infant which had been born a few hours before. The mother, when nearly at the end of her term, had been very severely scalded on the arms and portions of the body by the upsetting of a kettle of boiling water. She was taken to the hospital, and very soon after admission gave birth to a dead child. This child was marked on various parts of the arms and body with peculiar livid patches, situated beneath the integument, the skin itself being unabraded and normal in appearance. We did not see the mother, but Dr. Wallace assured us that he had examined both very carefully, and that the patches on the child corresponded exactly in outline and situation to the scalds upon the mother. This case impressed me most forcibly at the time. The lecturer called it a very remarkable coincidence, but it seemed to me then, and does still, that it required greater credulity to look upon the occurrence as a coincidence than it did to regard it as the result of some as yet unrecognized natural law; and I thought the wiser course would be to endeavor to discover this law and to trace its operations than to dismiss the case as a medical curiosity.

My purpose this evening, therefore, is to present to you certain facts, or alleged coincidences, either gleaned from medical literature or which have come under my own observation, which have led me to believe that the popular notion that the development of the fœtus is influenced by maternal impressions is one which contains at least a germ of truth, and which, therefore, is not unworthy of study by scientific men.

In the case to which I have just referred the markings upon the child could not, it is true, be attributed to mental impressions, for they corresponded to actual lesions upon the body of the mother. But if physical injuries, received toward the end of pregnancy, can be so rapidly photographed upon the body of the unborn child (for, as I remember the case, less than twenty-four hours had elapsed between the scalding of the mother and the birth of her infant), why might not mental injuries, continuing through weeks or even months, likewise impress their image upon the plastic frame of the fœtus? We

[1] A paper read before the Orthopædic Section of the New York Academy of Medicine, December 17, 1886.

are ready to admit the influence of the mind upon the body of the same individual, and have even classed by themselves the deformities and other physical ailments of hysteria; hypnotism and mental suggestion are beginning to assume an important place in the therapeutics, not only of mind diseases and various neuroses, but even of what we are wont to consider physical maladies. We cannot deny that diseases of the mother can be transmitted to the child in her womb; and we note the similarity in form, feature, and mental characteristics between parent and offspring; why, then, is it *à priori* so absurd to ascribe certain physical defects in the child to morbid mental impressions on the part of the mother?

"Probability," says Butler, "is the guide of life," and it is only by considering the weight of probability on one side or the other of a question that we are able to come to any definite or satisfactory conclusions. At first sight, I admit, it seems highly improbable that abnormalities in the growth or development of the fœtus can be caused by purely mental processes, apart from any actual disease on the part of the mother; and one single occurrence or a dozen occurrences, apparently establishing a relation of this sort of cause and effect, should have little weight in upsetting this antecedent improbability. But when facts of this nature can be counted, not singly or by dozens, but by scores and hundreds, we are forced to believe that possibly they are not mere coincidences, but may be expressions of an etiological law. I venture to assert that there is hardly a physician, of even a few years' experience, who has not met with some instances of this sort; they are for the most part regarded as rather strange coincidences, and are perhaps only mentioned in casual conversation among the other curious experiences of a doctor's life; but if one could collect the aggregate experience of the profession in such matters, it would, I doubt not, serve to convince even the most sceptical that, explain it how he might, maternal impressions do sometimes influence the physical development of the fœtus. In the very hasty glance which I have been able to make through a portion of the more recent periodical literature, I have read accounts of nearly two hundred more or less striking instances of this nature, and they are unquestionally but a small part of the supposed coincidences which have been met with, but which were not deemed worthy of record. I shall not inflict upon you the recital of all these cases, but will beg your indulgence for a very few moments while I relate three or four to serve as samples of the rest.

A lady brought her baby, aged a few months, to me for treatment. The child, perfectly healthy and well formed in every other respect, had a very pronounced talipes equino-varus of the left side. The mother said that, very early in her pregnancy, her husband was brought home one day, having fallen and broken his ankle. As she saw him brought into the house, his shoe and stocking having been cut off, she noticed the foot turned to the inner side. It naturally startled her considerably, and for months she dwelt on the occurrence, having the picture of the displaced foot always in her mind.

Mr. Crickmay has related in the *British Medical Journal*, May 29, 1886, that a man came to him, holding up his right arm, the hand of which had been obliquely severed by the knife of a chaff-cutter, leaving only a small portion of the thumb. A woman about two months advanced in pregnancy heard next day the details of this accident. She felt very sorry for the man's misfortune and experienced great distress when repeating an account of the occurrence to some friends. In due course of time this woman was delivered of a male child whose arm was without a hand, the stump, however, bearing the rudiment of a thumb. In the same journal, under date of September 1, 1877, Dr. Augustus Hess tells of a young married lady, in France, who lived in constant fear that her husband, who was a man of obstinate will, would fulfil a threat which he had made to chop off the thumb of his left hand in order to avoid military service in case he was conscripted. While this fear still preyed on her mind she became pregnant and gave birth to a child, who was well formed in every respect except that the thumb of the left hand was missing.

The following case, from the same paper, of the issue of November 3, 1877, is very striking by reason of the peculiar nature of the deformity. Dr. Jasper Cargill writes: "A lady in the early stage of pregnancy sent for me one morning to see her little boy, aged three years, in consequence of a puppy having bitten the glans penis. There was some swelling of the parts, which bent the penis in such a manner as to cause the child to micturate backward between the thighs. The mother was very much alarmed at the time. I attended this lady in her confinement. Two days afterward I was requested by the nurse to examine the baby (a boy), because the penis was found to be deformed. The glans was quite round and bent, and the meatus looked backward, precisely resembling the little boy's penis which had been bitten by the puppy."

M. Jules Guérin related to the French Academy of Medicine a rather curious case, in which the causation of the deformity might perhaps be referred to heredity, but which, I think, is rather an illustration of the influence of maternal impressions. Indeed, I am not sure that many, if not most, of the odd deformities which we sometimes see running in families may not be more justly attributed to the influence of maternal impressions than to heredity. I anticipate here the objection which has been raised by many, that deformities occurring in the lower animals are not infrequently transmitted to their offspring. But I fail to see the force of this argument, for why cannot a cat or a cow have mental impressions? Sir John Lubbock has given us many examples of an instinct—if you wish to call it by that name—in animals which is apparently of a higher order than the intelligence exhibited by some of our fellow-creatures. But you say, perhaps, that animals are not so observant as to notice deformities in their fellows. They are, however, observant enough to recognize each other, and to distinguish between friends and strangers. Even the ants in a densely populated hill can tell at once a member of their community from a stranger. If animals can do this they must be able to recognize differences in form and figure (I do not forget that the sense of smell is also an important aid); and why should they not therefore be cognizant of deformities in themselves and others?

A remarkable instance tending to prove the influence of maternal impressions in the lower animals is cited by Spitzka, in his work on insanity. "At the meeting of the Zoological Society of London, held February 24, 1863, Dr. C. E. Gray, the curator of the British Museum, presented the body of a chicken whose beak and feet closely resembled those of a parrot. The sender of the specimen reported that several such instances had occurred in his poultry-yard, and he attributed the monstrosities to the fact that one of the hens had been frightened by a parrot, which was kept in a cage in the same yard, and which had the habit, when the hens approached its cage for food, of screeching violently at them."

But to return to the case cited by M. Guérin, and which I find related in the *Gazzetta degli Ospitali* of February 21, 1886. He presented to the Academy a women and her three children, each of whom had a deformity of both hands consisting of an angular deviation of the index-fingers, the second phalanx forming a right angle with the axis of the first. The mother of this woman had the same malformation, and the woman herself at each pregnancy was greatly worried by the fear that her child would be similarly deformed.[1]

[1] Dr. J. G. Peters has called my attention to two cases of double monstrosity, related by Mr. F. Le Gros Clark in the St. Thomas Hospital Reports. The mother, in each instance, was, at about the time she became pregnant, very strongly and disagreeably impressed by representations of the "double-headed nightingale," who was then on exhibition. The fœtus, in each case, was double as to its upper portion and resembled the monstrosity which was the cause of the maternal impression.]

I feel some hesitation in speaking of congenital nævi and erectile tumors, the so-called mother's marks, for these have been made the special object of ridicule by those who believe the mother is an impassive agent in the production of her offspring—a sort of creative automaton. But the occurrence of birthmarks is, I maintain, often attributable to maternal impressions, although, of course, I do not pretend to say that every spot or blemish on the skin of an infant, any more than every congenital deformity, is due to this one cause. I will instance but one case of this nature, which is related by M. de Saint-Germain, who himself is an opponent of this theory, in his "Chirurgie Orthopédique." While he was in charge of the maternity service at the Hôpital Cochin, a woman was admitted who was in great distress, saying that she was to give birth to a squirrel. She related that toward the end of her fourth month, while she was passing a bird-fancier's, a squirrel leaped from its cage onto her shoulders, giving her a great fright. She was delivered at term of a fine child, who presented along the spinal column, from the seventh cervical vertebra to the coccyx, about forty long red hairs, like those on the back of a squirrel. Those hairs were not permanent, but fell off at the end of a certain time.

A case in which there was congenital absence of hair is narrated by Dr. William T. Taylor in the *Philadelphia Medical Times* of November 15, 1876: "A medical man told me that one of his children had a bald spot on its head, which his wife says arose from the circumstance that, in the early months of her pregnancy, she was frequently looking at the shining bald head of her father-in-law, with an unaccountable delight."

Several cases of birthmarks, possibly due to maternal impressions, are related by Tuke in his work on the "Influence of the Mind upon the Body."

Dr. F. K. Bailey related a case, somewhat similar to that mentioned in the beginning of this article, in the *Medical and Surgical Reporter* of May 31, 1873. A lady who was pregnant came under his care for severe neuralgia. A blister was applied near the trochanter major. On the birth of the child there was plainly seen a brownish spot, exactly corresponding in shape and locality with the blister which had been formed on the mother's thigh. The child lived thirty days, and the discolored spot remained distinctly visible during this time.

I may anticipate here two objections which are frequently raised by disbelievers in the theory which we are discussing. I think it is Darwin, in his work on "Plants and Animals under Domestication," who relates that Hunter made a practice of asking every woman, before her delivery, whether she had any reason to suppose that her child would be deformed or marked in any way. He made inquiries in about two thousand cases, and in no case did the deformity in the child correspond to the mother's fears. In the *American Journal of Insanity* for January, 1870, Dr. Fisher states that he made such inquiries in every case occurring in his practice during a period of twenty years, and though many women expressed their fears, and even described the malformation which they anticipated that their children would bear, he met with but two cases of congenital deformity; and even in these cases there was no apparent correspondence between the malformation and the mother's apprehension.

This is, I admit, strong negative evidence, but negative evidence carries less weight than does positive testimony; and two hundred cases in which the malformation of the infant corresponded to the fears of the mother, expressed before the birth of her child, should, I think, be held to argue more strongly in favor of this theory than two thousand cases in which no such correspondence existed could argue against it.

The second objection is one that has been raised by some German investigators, who examined into a number of alleged instances of maternal impressions, testing them by the known facts of embryology. They found in many cases that the arrest of development must have occurred at a time long before that at which the mental shock was received, and thus proved that such malformations could not have been caused by the fright of the mother. But, while I recognize the force of this argument in certain cases, I cannot see that it disproves the theory. It is not contended that every congenital malformation is the direct result of a maternal impression, any more than it is that every thought or idea originating in the mind of a pregnant woman must of necessity have its influence upon the development of the child in utero. The cases to which I refer especially this evening are not those of arrested development from a sudden shock, but rather of perverted development resulting from a fixed and long-continued mental impression. That the relation of cause and effect can be disproved in a certain series of cases is not sufficient to warrant us in rejecting presumptive evidence in favor of this relation in other cases.

Let us suppose that a child is known to have been exposed to the contagion of measles, and that this child goes home and is seized at once with a disease presenting all the symptoms of this same malady. We would say that the child could not have acquired the disease from this known exposure, because there was no appreciable period of incubation, but we would not be warranted in assuming that measles is not contagious. We could only say that there must have been some previous exposure. And so it is in the cases quoted by the German observers; the malformations in these instances could not have been caused by the known maternal impressions, but they were to be referred to some other cause acting at an earlier period. This simile is, perhaps, not very apt, but it will serve, I think, to explain my meaning.

It is not my purpose this evening to discuss at length, even were I able to do so, the manner in which the mental action of the mother influences the growth and development of the child. We know as yet too little of normal embryology and fœtal growth to discuss satisfactorily the pathological side of reproduction, and my object has been rather to suggest to you the possible importance of one factor in the etiology of congenital deformities, reserving the consideration of its *modus faciendi* for another occasion. I cannot, however, pass this subject by entirely, for a rational explanation of a seemingly remarkable occurrence goes more than halfway toward removing the difficulties which we experience in accepting it.

Brodhurst says that congenital deformities are due to arrest of development, to increased development, or to muscular spasm in the fœtus. This would answer, perhaps, as an explanation of the occurrence of deformities strictly so called, although I think he might better have substituted the term perverted development, which would include certain cases in which there is neither an arrest nor an increase. But in order to more easily explain the subject we must go beyond the title of this paper, and include under the term deformities all congenital deviations from the normal, whether mental or physical. This is the more necessary since we are dealing with a something which, whatever may be its subsequent phases, originates in the cerebral cells of the mother; and we may, therefore, not unreasonably expect, from a study of nervous aberrations of congenital origin, to derive some assistance toward a better comprehension of the malformations of the body.

Congenital idiocy is acknowledged by many authorities to be very frequently a result of violent temporary emotion, or of a more prolonged but less vivid mental disturbance, such as grief or anxiety, on the part of the mother during her pregnancy. But idiocy is almost always accompanied by asymmetry of cerebral development, cranial malformation, or even club-foot or other gross deformities. Now, if idiocy may be caused by psychical troubles of the mother, why may not also the malformations which accompany, or may even be the direct occasion of, the mental disturbance be fairly attributable to the same influence?

Chorea may, in very rare instances, be congenital. Putzel has collected eight cases reported by various observers, in four of which the probable exciting cause was mentioned. "In Mayo's case the mother had been extremely nervous for a period of two months after a disgusting object had been thrown upon her bosom (while she was four months advanced in pregnancy). In Richter's two cases, the mothers had been very much frightened shortly before confinement. Spamer mentions, with regard to his case, that the mother had been very nervous and depressed, during the entire period of pregnancy, on account of the death of one of her children."

Dr. E. H. Addenbrooke relates the following instance of congenital facial paralysis caused by maternal impressions (*British Medical Journal*, May 13, 1871). "A few weeks since, while attending Miss B——, I noticed that her mother suffered from paralysis of the muscles of the left side of the face. Mrs. B—— informed me that the affection was congenital, and gave me the following history: Her mother and her mother's sister (both of them pregnant) were staying with Mrs. B——'s grandmother, nursing her in her last illness. One night, as they were both assisting her to the night-stool, the old lady was suddenly seized with hemiplegia, the facial paralysis being specially noticed by them. Both daughters were confined three or four months afterward, and each of the children suffered from congenital facial paralysis of the left side. Mrs. B—— tells me that she has often seen her cousin, and that she is afflicted in precisely the same way as herself. The two mothers often used to lament together over their children's deformity."

A classical instance of a mental peculiarity apparently traceable to maternal influences is that of King James I. Sir Kenelm Digby[1] relates that the king had a great dread of a drawn sword, and attributes it to the fright which Queen Mary received while pregnant, when she witnessed the murder of Rizzio. When Sir Kenelm was knighted by James, the latter, he says, could not look at the sword, and "he had almost thrust the point into my eye, had not the Duke of Buckingham guided his hand aright." Another case somewhat similar to this is narrated by Dr. E. Seguin in the *Philadelphia Medical Times* of December 23, 1876.

The following instance of eclampsia from maternal impressions, related by Dr. Bailey in the *Medical and Surgical Reporter* of May 31, 1873, is suggestive. A pregnant woman nursed her son, seven years old, through an attack of cerebro-spinal meningitis. The convulsive seizures were frequent and severe. Her infant, when born, was well developed in every way, but had spasms every time his bowels moved; the face would become livid, the head was thrown back, and episthotonus was marked, the eclamptic attacks resembling precisely those from which his brother had suffered. The affection disappeared in about a year.

It is a recognized fact that convulsions in nursing infants may be produced by mental excitement of the mother or nurse. Now, if a mental disturbance on the part of the mother may so affect her milk as to make it poisonous to the child, it does not seem unreasonable to suppose that the blood of the pregnant woman may, in like manner, become changed so as to act injuriously upon the fœtus. It makes no difference, in the first case, whether the milk becomes simply indigestible and thus excites eclampsia reflexly, or whether it contains some poisonous principle which enters the blood and acts directly upon the nervous centres. Its composition is changed, and changed as a consequence of the undue cerebral activity of the mother. The mental impressions of the pregnant woman act, I believe, in a similar way upon the fœtus. The blood of the mother is altered, or receives upon it some impression, the nature of which we have at present no way of determining, and perhaps may never learn, but which induces like changes in the blood of the embryo; and this in turn acts upon the nerve-centres, and thence upon some special organ or part of the fœtal body to which the mind of the mother was specially directed. I do not refer now to those cases in which some sudden and momentary mental shock causes the death of the child, arrests its development, or induces abortion; but to the less coarse changes, resulting from continued mental concentration, and which are manifested by some localized mental or physical defect of the infant. The gross derangements of the embryo may, indeed, be produced in the same way through the placental circulation, but they are less evidently the result of a special mental process on the part of the mother.

Dalton says in his "Human Physiology": "There is little room for doubt that various deformities and deficiencies of the fœtus, conformably to the popular belief, originate, in certain cases, from nervous impressions experienced by the mother. The mode in which these effects may be produced is readily understood from the anatomy and functions of the placenta. It is well known how easily nervous impressions will disturb the circulation of the brain, the face, or the lungs; and the uterine circulation is quite as readily influenced by similar causes, as shown in cases of amenorrhœa and menorrhagia. If a nervous shock may excite premature contraction in the muscular fibres of the pregnant uterus and produce abortion, it is undoubtedly capable of disturbing the circulation of the blood in the same organ. But the fœtal circulation is dependent, to a great extent, on the maternal. The two sets of vessels are united in the placenta, and as the fœtal blood has much the same relation to the maternal that the blood in the pulmonary capillaries has to the air in the pulmonary air-cells, it must be liable to derangement from similar causes. And, lastly, as the nutrition of the fœtus is provided for wholly by the placenta, it will suffer from any disturbance of the placental circulation. These effects may be manifested either in the general atrophy and death of the fœtus, or in the imperfect development of particular parts; just as in the adult a morbid action may operate upon the entire system, or may show itself in some one organ, which is more particularly sensitive to its influence."

The following case, related by Dr. Robert B. Carter in his work on the "Pathology and Treatment of Hysteria," is an illustration of how a mental impression can occasion a local lesion. "A lady who was watching her little child at play, saw a heavy window-sash fall upon his hand, cutting off three of his fingers, and she was so much overcome by fright and distress as to be unable to render him any assistance. A surgeon was speedily obtained, who, having dressed the wounds, turned himself to the mother, whom he found seated, moaning and complaining of pain in the hand. On examination three fingers, corresponding to those injured in the child, were discovered to be swollen and inflamed, although they had ailed nothing prior to the accident. In four-and-twenty hours incisions were made into them and pus was evacuated; sloughs were afterward discharged, and the wounds ultimately healed."

We know that there is a more intimate connection between the embryo and its mother than is evidenced by the anatomical relations which we are able to trace. It is the common experience of stock-raisers and dog-fanciers that a female which has had young by a male of another race will never breed true again. Any young which she may subsequently have will betray some characteristics of the male parent of the first progeny.[1] Thus the fœtus impresses upon its mother some indelible change, primarily in the blood and then probably in the nerve-cells. But if the fœtus can thus influence the nerve-cells of the mother, it is reasonable, especially in the light of the facts

[1] A late Discourse made in a Solemne Assembly of Nobles and Learned Men at Montpellier, in France. Rendered faithfully out of French into English by R. White. London, 1658.

[1] A number of instances of this sort, occurring in the human species as well as in the lower animals, are related in a recent interesting work by Dr. Alexander Harvey, entitled, On the Fœtus in Utero, as Inoculating the Maternal with the Peculiarities of the Paternal Organism.

which we see repeated around us, to conclude that the nerve-cells of the mother can influence the growth and development, mental or physical, of the embryo.

Of course, I do not pretend to maintain that maternal impressions are the cause of all congenital deformities, or even of many: indeed, I believe that very few of the malformations seen in the new-born child are so produced. And it is fortunate that it is so, for were every pregnant woman who has received a strong mental shock, or whose thoughts have run in one particular channel for any length of time, to give birth to a deformed child, humanity would present a sad spectacle indeed. But I do believe, and I think my belief rests upon a strong foundation of facts, that the mental impressions of the mother oftentimes react, for good or for bad, upon the growing form of the child in her womb. A violent nervous shock is liable to cause the death or arrest of development of the embryo; a less severe, but more prolonged, mental impression may occasion a perversion of development. In the first case, if the child live, it will be a monstrosity; in the second case, it will be simply deformed in some part, and the peculiar nature of the deformity, or the part affected, will be determined by the nature of the mental process on the part of the mother. The concentration of her thoughts upon some particular anatomical portion may cause that portion of the child to assume the shape corresponding to the appearance that exists in the mother's mind. In the first case, the blood is so altered as to be actually poisonous to the growing embryo. In the second case, it is the medium for transmitting nervous actions from the mother to the child; and that child's nervous system is then placed in a condition similar to that of an hysterical woman, in whom a particular part of the body may become deformed or the seat of inflammatory changes from purely nervous causes.

102 East Fifty-seventh Street.

REPORT OF A CASE OF TYPHOID FEVER IN WHICH ANTIFEBRIN WAS USED SUCCESSFULLY AS AN ANTIPYRETIC AGENT.

By GEORGE R. ELLIOTT, M.D.,

NEW YORK.

The patient had well-marked typhoid fever. Antifebrin was the successful antipyretic agent employed after other antipyretic means had failed. The effect of this drug was so wonderful that I feel no apology is necessary for briefly reporting its use in the following case:

Mr. C. J. Bishop, aged twenty-one, an actor of prominence, arrived from San Francisco during the last week of October complaining of anorexia, malaise, headache, and febrile symptoms, which moderately large doses of quinine had failed to relieve. I was asked to assume charge of this patient by Dr. J. H. Douglas, and saw Mr. Bishop for the first time on the morning of October 31, 1886. In the father of the patient, Dr. C. B. Bishop, I found a medical gentleman of unusual skill and acquirements, and so endeared to his son that no symptom was overlooked and every detail in treatment was rigidly carried out. The drinking of well-water in Southern California was the probable etiological factor in the production of the disease.

As near as we could estimate, it was the seventh day of the disease. The thermometer registered 104⅖° in the mouth at 5.30 P.M.; pulse 104, with a fairly good tension. The abdominal symptoms were negative, excepting enlargement of the spleen. There was moderately profuse bronchitis. Having had malarial attacks previously, it was a question whether or not malarial miasm was complicating the present difficulty.

He was moderately purged with triturated calomel and ordered to have thirty grains of quinine during the night in divided doses of fifteen grains each, and diet to be liquid in character. With the following day came only marked cinchonism as a result of the thirty grains of quinine. The temperature showed a morning remission of 1° F. He had during the night six liquid stools of a greenish black color. By evening the temperature had again reached 104⅘°. Cold sponging was frequently resorted to, much to the comfort of the patient. The quinine was repeated at night, and again only cinchonism manifested itself as a result. The thermometer showed no morning remission. The following night we decided to give forty grains of quinine in divided doses of twenty grains each; only one dose was given, as depression of the heart's action, accompanied by dyspnœa, followed its administration. The temperature remained the same. I was satisfied that we had excluded a possible malarial element and were dealing with an unquestionable case of typhoid fever. By this time the typhoid symptoms were quite well marked. The temperature was characteristic; the stools were frequent and of a typhoid character; there was moderate tympanitis; an enlarged spleen; well-defined bronchitis; a tremulous tongue, and "facies" unmistakable. The eruption, which was absent at the time, occurred later. The further use of quinine was abandoned, for in our experience, as an antipyretic agent in typhoid fever it is useless. I have repeatedly employed it in a large number of cases of typhoid fever in hospital practice with the prime object in view of testing its efficacy as an antipyretic agent, and can positively state that in no single instance have I ever seen it reduce temperature. In all cases when it did so act, an unmistakable malarial element has been proven to exist. From this time on for several days we resorted mainly to the use of cold to partially control the temperature.

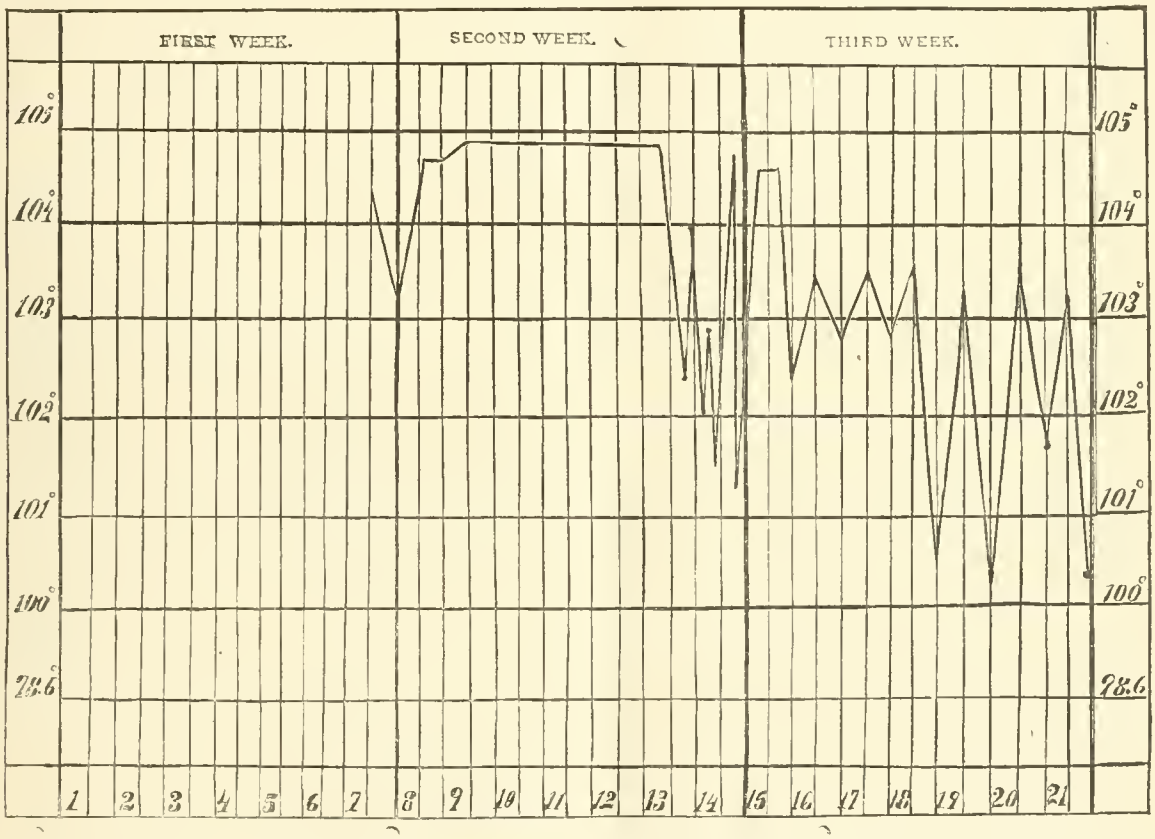
The latter had become the continuous temperature of the second week (104⅘°), but without any morning remission. The patient began to show the result of this high temperature by delirium, and marked subsultus tendinum. It was evident that unless the temperature could be controlled the prognosis was rendered correspondingly more grave. We decided to try the efficacy of antifebrin, a new remedy which had been discovered in Germany, and for which much was claimed as an antipyretic agent. It was especially claimed that it had no depressing effect upon the heart, herein a superiority over antipyrin, and, unlike that drug, surrounded by no mystery, and its chemical composition barred by no seal from the knowledge of the profession.

The attention of the profession was first called to antifebrin by Drs. A. Cahn and P. Hepp, assistants at Kussmaul's clinic, in Strassburg, in an article which appeared in the *Centralblatt für Klinische Medicin*, No. 33, of August 14, 1886. Antifebrin is chemically designated as an acetanilid, and has the formula $C_6H_5NHC_2H_3O$. It is a clear, white, crystalline substance, odorless, nearly insoluble in cold water, slightly soluble in warm water, and freely soluble in alcohol and alcoholic solutions. Drs. Cahn and Hepp report, as a result of their experimentation, that relatively large doses can be given to animals without producing any poisonous effects, and that the normal temperature is not affected by its use. They used it in twenty-four cases where high temperature predominated, including typhoid fever, erysipelas, rheumatism, and septicæmia, and report that in every instance they were successful in reducing the temperature without any disagreeable effects following. In no case was it found necessary to give more than thirty grains during twenty-four hours.

Hand-in-hand with the temperature fall was noticed a *diminished frequency* of the pulse-rate, accompanied by increased arterial tension, the latter founded upon carefully taken sphygmographic tracings. No nausea, vomiting, or diarrhœa followed the use of the drug. It is interesting to know how the drug acts. The antipyretics heretofore known are either phenols (carbolic acid, salicylic acid, etc.), or they are bases, and belong to the chinolin

series (chinin, thallin, etc.), while here for the first time we are dealing with an indifferent substance which in composition is widely separated from the others. For further information the reader is referred to the original article. I obtained some antifebrin from Fraser & Co., 208 Fifth Avenue, and ordered four grains to be administered at 4 P.M., 7 P.M., and 10 P.M., respectively, in the evening of November 5th, the twelfth day of the disease, with the following result: The temperature at the time of giving the first dose was 104⅘°, pulse 115. Half an hour after administering the second dose the patient began to perspire profusely, and at eight o'clock *the temperature had fallen to* 102½°. The pulse had not varied in frequency, but its tension had slightly increased. The reduction of the temperature was attended by an amelioration of the symptoms. The mind became clear and the patient conversed rationally. At ten o'clock the temperature had reached 104°, and another dose of four grains was given, with a repetition of what followed the second dose, viz., the temperature falling to 102°, accompanied by profuse perspiration, subsidence of the delirium, and a return to consciousness. Twice now had we administered antifebrin to our delirious patient, a delirium which quinine had seemed to deepen, and as many times we were met with a rapid return to consciousness. After this the temperature was not allowed to go above 103°, and the mind remained clear.

On November 10th, the seventeenth day of the disease, there seemed to be a morning remission, and antifebrin was discontinued. I may state here that at no time had we found it necessary to give more than twenty grains during twenty-four hours. Stimulants were used sparingly, the character of the pulse, which was dicrotic, being made our guide for their use. With the morning of November 11th came again a morning remission. The case seemed now to be progressing favorably through the close of the third week, and we congratulated ourselves upon having warded off one of the worst elements of typhoid fever, high temperature, and its retinue of complications. The first sound of the heart was good.



companied by copious perspiration, and no perceptible bad effect upon the heart. The temperature began to rise again at midnight, and at 3.30 A.M. had reached 103⅘°. Four grains of antifebrin were given, and exactly at the end of thirty minutes there was profuse perspiration, accompanied by a fall of temperature which at 5.30 A.M. *was only* 101⅘°. At 3.15 P.M. the temperature was 104⅗°, pulse 115; and another dose of antifebrin was given. Mark again the result: At 4.30 the temperature was 101⅖°, pulse 95, with tension improved; by midnight temperature was 104⅖°, pulse 120. Wishing to exclude a possible coincidence in the reduction of temperature and the administration of the antifebrin, we resolved again to try quinine in large doses and gave fifteen grains, repeating same in four hours. No effect upon the fever followed its use. The mind, which had been clear as a result of keeping the temperature low, again became clouded, accompanied by low muttering delirium, subsultus tendinum, and an evident deepening of all the typhoid symptoms. Antifebrin was now given, and in two hours the temperature had dropped to 101⅕°, Everything progressed favorably up to the afternoon of the 14th, when, after a stool, our patient was seized with violent abdominal cramps, followed by profound collapse, out of which it was impossible to rally him, and he died during the afternoon of the following day. The collapse appeared to be due to intestinal perforation.

The reader will, doubtless, ask himself what we asked ourselves—was this collapse in any way traceable to the action of the drug? Let us see. Five days had elapsed between the discontinuance of the antifebrin (no further indication for its use seeming necessary) and the fatal collapse. During this time convalescence appeared unquestionably to be establishing itself. Dr. Bishop, who had watched his son so faithfully, who had noted and carefully recorded every change in the pulse, temperature, mind, etc., while sorely grieved at the death of his son, agreed fully with Dr. Douglas and myself that the action of the antifebrin had been simply wonderful, and that no possible relationship could be established between its use and the fatal result. We had reduced a fever which had been continuous for one week, and, as

the record shows, would have remained continuous for nearly one week longer. This had been accomplished without any apparent depression, and our patient carried along with a clear mind. Had we not bridged a dangerous period?

During the course of the disease there were two complications, to which I will merely allude: 1. A bronchitis so profuse that at times it threatened to seriously affect the progress of the disease, and from time to time moderate counter-irritation was resorted to, and internally small doses of carbonate of ammonia were given. 2. An intestinal hemorrhage the seventeenth day of the disease, the patient passing about one ounce of arterial blood. This hemorrhage was controlled and did not recur. These complications, together with a continuous high temperature during the second and third weeks, which showed *no tendency to a morning remission*, indicate the malignant nature of the poison with which we were dealing. I have purposely deferred entering more into detail, such as giving the character of the pulse and respiration from day to day, number of stools, etc., confining myself principally to the character of the fever and the effect of the antipyretic agent employed. I have endeavored to give a truthful description of the same without exaggerating a single incident, and I feel assured that Dr. Bishop and Dr. Douglas will corroborate the statements I have made.

The effect we met with is doubtless too flattering to expect in all cases where antifebrin is used. Its value and place in our materia medica will soon be determined and its level reached. If in it we find, as it promises, a safe and certain antipyretic, we can say indeed with the ones who originally called the attention of the profession to it, "*Ein glücklicher Zufall hat uns ein Präparat in die Hand gespielt, an dem wir ausgezeichnete antipyretische Wirkungen entdeckten.*"

"GRASS STAGGERS."—Dr. J. W. Carhart, of Lampasas, Tex., writes: "I notice, under the above caption, an item in THE MEDICAL RECORD, of October 23, 1886, referring to an article in the *Cornhill Magazine* on cowboys in Texas, in which there is a statement with reference to the poisonous effects of what is known in Northwest Texas as the loco weed. Having spent a year and a half in that portion of Texas lying between the Indian Territory and New Mexico, and known as the Panhandle, I am familiar with the weed so well described in the *Cornhill Magazine*, and with its effects on horses. Cattle occasionally eat it, but are rarely affected by it. I never knew mules to suffer from it, but cow-ponies are destroyed by it every year in that country by the thousand from eating the weed. When they have once acquired a taste for it, they will leave fresh, green grass to hunt and eat the loco weed. They break down very rapidly under its effects. They at first fall away in flesh, the hair assumes a dead and dirty appearance. They soon become weak and staggering, and if they continue to eat it they become, in cow-boy parlance, 'plumb fools.' They are often perfectly crazy. A gentle tap of the hand on the top of the head of a 'locoed' horse will cause him to stagger, rear, and fall backward. Vision is impaired, and there is an evident loss of muscular coordination. The Indians say that the effect of the weed is due to an insect infesting it. But I have examined specimens under a powerful glass, and found no insect. I made a decoction of the plant and drank it without apparent effect. I gave the decoction to 'locoed' horses and it had a beneficial effect, on the principle, I suppose, of *similia similibus curantur*, but could not keep them sufficiently long under observation to prove a cure. There can be no doubt about the abundance of the weed in certain regions of the West, or of its effects. The ergot of smutty corn produces blind staggers in horses, from the constricting effect on the blood vessels of the brain. The objective symptoms of loco-poisoning are similar."

A CASE OF MIXED ROUND- AND SPINDLE-CELLED SARCOMA OF RETRO-PERITONEAL GLANDS, CORDA EQUINA, NERVE-ROOTS, DURA OF SPINE AND BRAIN, PONS, MEDULLA AND CORPORA STRIATA.[1]

BY RICHARD VAN SANTVOORD, M.D.,

NEW YORK.

K. B——, a woman aged thirty-four, was admitted to the Randall's Island Hospital, September 8, 1886. She was apathetic and not able to give a very good account of her previous history or present sufferings. It was learned, however, that she had suffered from pain in her right lower extremity. On admission she complained of intense pain in the left lower extremity. She was unable to define its character, nor did it seem to follow any definite nerve-distribution. The left leg was slightly smaller than the right, the thigh being one inch less in circumference. No anæsthesia was present. Reflexes, electrical reactions, and strength were not tested. The patient could, however, move her legs. She complained also of abdominal pain. A firm, large mass, whose outlines could not be very accurately defined, was found, presenting a little above and to the right of the umbilicus and separated by a line of resonance from the liver. It was more or less distinct according as the intestines were less or more distended. The patient failed rapidly. Four days before death she became unable to use her legs and could not pass her urine. Her mental apathy had become so great that no tests of sensibility could be relied on. Death resulted apparently from the pressure effects of the abdominal tumor, nineteen days after admission. The autopsy showed moderately-firm, wart-like growths on the inner surface of the cerebral dura, one about the size of a large pea in the right anterior fossa, two smaller ones on the under surface of the tentorium at each outer angle, and one about the size of a large pea over the body of the sphenoid, obviously compressing the pons. The cerebral arachnoid showed slight chronic thickening. In each lenticular nucleus was a small growth, the size of a medium-sized pea, that in the right being surrounded by a small area of softening. There were two growths, about the size of large pin-heads, on the anterior surface of the pons, under the pia. A similar growth existed on the surface of one of the anterior pyramids of the medulla. A small growth, the size of a buckshot, was found on the surface of the cerebellum. It was apparently a fragment of one of the tumors of the tentorium which had become adherent to the pia and been cut off in removing the brain. The roots of several of the cervical nerves, and, more prominently, some in the dorsal part of the cord, were involved in yellowish-gray infiltration from their points of egress from the dura to where they had been cut off. In the corda equina of the left side, within the dura, the nerves were involved in a firm, irregular mass about the size of a plum pit. A smaller mass similarly involved some of the nerves on the right side. At point of egress from the dura these nerves were thickened and yellowish on section. The left sciatic was removed from its point of egress from the sacral foramina to the knee. The induration extended to the junction of the roots, but could not be detected lower down. A pea-sized outgrowth projected from the dura over the middle of the anterior surface of the cord. The pia of the cord showed recent fibrinous exudation. Opposite the outgrowth from the dura the cord was very soft. The greater part of the cord below and for some distance above this point was also abnormally soft. A wedge-shaped section sawed from the lumbar vertebræ, and the opened spinal canal, were examined in vain for evidences of morbid growth. The posterior surface of the sacral canal looked slightly eroded and was coated with fibrinous material. The lungs

[1] Read before the Section in Neurology of the Academy of Medicine, November 12, 1886.

were œdematous and slightly adherent. The heart was small and brownish; slight atheroma of aorta. Two or three small yellow nodules were found in the liver. On the under surface of the right lobe was a yellowish mass, size of a walnut, filled with yellow pasty matter, containing hydatid hooklets and convoluted cyst-walls. A large mass, size of a cocoanut, was found behind the peritoneum, extending a little more to the right than to the left of the median line. Its anterior fifth was a cyst, with irregular walls, containing clear yellowish fluid and translucent yellowish coagula. The body of the tumor was made up of firm whitish tissue.

The kidneys and intestines presented no noteworthy lesions.

The microscope showed that the retro-peritoneal tumor consisted of lymphoid and spindle-cells, with an intermixture of large round cells. It also included some fat which was infiltrated with lymphoid cells. A nerve-root with adjacent dura showed infiltration with round cells in the dura and irregularly through the nerve-root, but most marked at its periphery. A few spindle-cells were also seen, and some irregular dilatation of the vessels. One of the tumors of the dura was found to be made up almost entirely of lymphoid cells, the spindle- and large round-cell element being very slight.

This case seemed to me worthy of presentation on account of the large number, and very unusual distribution, of the neoplasms. The primary growth was probably the retro-peritoneal, judging from its size. According to Virchow, primary retro-peritoneal sarcoma is usually single, its injurious effects being produced only by pressure. Sarcomata of the dura are, according to the same authority, usually single, though occasionally two or more are found. They are usually spindle-celled.

Under the head of neuroma Virchow describes several cases in which there have been multiple tumors of nerve-roots, and as several of these were old, imperfectly reported cases, it seems possible that they may have been sarcomata. I have failed to find any undoubted case of multiple sarcomata of the nerve-roots. In *Brain*, for January, 1886, Dr. S. Harris reports a case of spindle-celled sarcoma of the corda equina, substance of the cord and medulla, with secondary growths in the pleuræ and pericardium. In multiplicity of growths this case is the nearest approach to my own that I have found, it being apparently true, as a general rule, that sarcomata of the nervous system are single.

The marked pain with atrophy in the left leg, together with a new-growth in the abdomen, lead me to suppose that the case was one of so-called paraplegia dolorosa, caused by pressure from new-growth in the vertebræ. As such pressure frequently results from neoplasms narrowing the vertebral foramina, a complete examination calls for the entire removal of the vertebræ, a procedure which, for prudential reasons, I did not care to undertake in this case. The tumors in the corda equina, however, seemed to account for the symptoms complained of, and the absence of disease in the vertebral bodies and surface of the spinal canal seemed sufficient to exclude disease of the bone.

Although sarcomata of the vertebræ occur, and may give rise to pressure upon the cord or nerves, yet they seem to be quite rare. Dr. Marcoe, however, in his work on diseases of the bones, records a case of spinal paralysis caused by pressure from a "spindle-celled fibroid" growing from a transverse process of one of the cervical vertebræ, which was cured by operation. Dr. Frank Ferguson mentioned to me a case which he had recently seen, in which a sarcomatous growth from the body of a vertebra had caused pressure on the cord, the case clinically having been regarded as depending on some lesion situated in the cord itself.

Judging from a somewhat imperfect review of the literature of the subject, it would seem, however, to be true that lesions of the spinal cord were more often, in the case of sarcomata, caused by tumors of the cord itself or its membranes than by outgrowths from the vertebræ, the reverse being true of sarcomata.

20 East 125th Street.

NOTES ON A CASE OF PERIPACHYMENINGITIS SPINALIS.

By WILLARD H. MORSE, M.D.,

WESTFIELD, N. J.

Peripachymeningitis spinalis is a disease of rare and serious occurrence. In looking diligently into the bibliography of the subject, I find but eight cases of this malady on record in either America or Europe. Of these eight cases, John Simon reported one, in 1855, in the "Transactions of the London Pathological Society" for that year; Traube reported two, in 1863, before the Medical Society of Berlin; Professor Mannkopf, in the following year, wrote of another case in the *Berliner Medicinische Wochenschrift;* Mueller, in 1868, gave an elaborate description of a case in a work which he issued at Königsberg, entitled "Ueber Peripachymeningitis Spinalis;" the *Klinik der Rueckenmarkskrankheiten* for July, 1876 (if I mistake not), contained a dissertation on a case, which, though from the pen of the elder Leyden, is very fragmentary and incomplete; the same authority, however, in the *Berliner Klinische Woehenschrift* for December 17, 1877, reports his second case, and in his paper makes further reference to the first; and, lastly, Dr. L. Putzel, of New York, reports a case in The Medical Record for January 26, 1878.

In taking these cases in review, I find some very interesting details. That reported by John Simon followed a spinal fracture, and among the several autopsical appearances revealed by the scalpel of that eminent observer were two abscesses at points outside of the spinal canal, and connecting with it through the intervertebral foramina, a fact held in proof that the abscess formations, occurring prior to the perimeningeal inflammation, were causative of it, and stood revealed in the presence of a deposit of pus along the whole length of the cord beneath the dura mater. Mannkopf's case had to do with a similar expression of etiology, though instead of abscesses the primary lesion was a deep-seated inflammation in the tracheal muscles, extending thence backward into the connective tissue between the dura mater and the first two dorsal vertebræ, where, on the left side, posteriorly, a tumor pressed upon the spinal cord, upon which it exerted no abnormal effect other than that caused by the item of pressure. Mueller's case was also one of extraneous origin, the primary seat of inflammation having been a subpleural sarcoma, from which the morbid action passed outward through an intervertebral foramen into the perimeningeal connective tissue. Of Leyden's two cases the first was manifestly due to an abscess near the left anterior superior spinous process of the ilium, and the second was brought about by an injury to the spine and left shoulder, eventuating in paraplegia and death. The post-mortem in the latter case showed a thick mass of exudation, compressing the cord to such an extent as to cause myelitis, extending from the third to the tenth dorsal vertebra, and entirely surrounding the dura mater. Dr. Putzel's patient dated his malady from a deep abscess of the neck, and after an experience of paralysis, hyperæsthesia, and abscesses, finally entirely recovered. These six cases were all secondary to inflammation outside of the spinal canal; but in Traube's cases there was in both instances that which evidently pointed to the primary development of the meningeal affection. In these cases the distinguished German pathologist noted the development of many minute abscesses in the deep spinal muscles some time subsequent to the pronounced primary development of the meningeal affection. To which of these categories belongs the case which I have to report is, to my mind, somewhat uncertain.

The patient was, at the time when he first came under my observation, a young man with a history that told emphatically of an hereditary and an acquired tendency to nervous diseases. Both of his grandfathers had died of apoplexy, one grandmother had been a long-time sufferer from melancholia, his mother was a paralytic, and during the time that he was under my care his father died of an apoplectic seizure. From infancy a weakly boy, he was possessed of a brilliant intellect, and at nineteen graduated from college. Six weeks later his physicians took him from his books and sent him to the Adirondacks, advising him that in their opinion a summer's vacation was needed to rid him of frequent attacks of headache, which they feared might terminate in an accession of his unfortunate grandmother's mental malady.

While in the woods he was exposed to a cold rain, and some nine hours after this exposure he began to suffer from a severe pain in his neck, on the right side. This soon extended into the upper dorsal regions. Upon his return from the woods his attendant put him under treatment for "torticollis." Failing of relief he came to me, when, upon examination, a swelling was found on the neck, on the right side. A diagnosis of deep-seated abscess of the neck was made, and decided febrile action was soon noticed. For three weeks he suffered from severe pain in the affected part, and at the end of the fourth week he suddenly became almost completely paralyzed on the corresponding side of the body. For nine days succeeding there was no change, but at the end of that time formication and tingling ensued, and under treatment by local faradization the condition of paralysis gradually gave way, disappearing almost entirely in the January following, fully five months after the initial treatment. Meanwhile the swelling in the neck had become reduced to a small indurated mass, but slightly sensitive to pressure. Before spring even this was overcome, and the paralysis having passed, the patient made a complete recovery. To my certain knowledge he was in a state of perfect health for three years following, having no return of the symptoms, and expressing himself as being in better health than ever before. Entering the bar, he became known as a rising lawyer. Marrying, he became the father of a promising son.

At the end of last October he presented himself for treatment for a series of cerebral and spinal symptoms, notably headache, vertigo, and insomnia, together with great muscular weakness of the back. It was the first trace of ill-health that he had had for thirty-four months, and, so far as could be ascertained, it was not referable to any apparent cause, unless something in the way of an abuse of alcohol had to do with it. These symptoms continued, without febrile motion, paralysis, or convulsions, and pointed, though imperfectly, to either cerebritis or meningitis. On the fifth day an attack of prolonged somnolency occurred, and as soon as this was in some degree obviated the patient began to complain of a feeling in the dorsal region which he characterized as "the pricking of many needles." An examination revealed several (eleven) swellings in various places in the right rhomboideus, which were hard, circumscribed, and immovable, but exquisitely tender to the touch. One of these, of a particularly painful character, was situated just at the level of the second dorsal vertebra, and as the patient complained of it more especially, it was opened, and discharged a small amount of dark, offensive pus. The next day two of the other abscesses were opened, one of these discharging a small piece of bone. Immediately upon this occurrence a convulsion took place, continuing forty seconds. Subsidence of movement and general relaxation ensued, a lateral jactitation of the head began, and three further convulsions followed. After the third of these the patient became quiet and unconscious. A condition of coma was the instant sequel, and after continuing ten hours there was a slight spasm, and death took place, the pulse having suffered no variation at any time in the final sixty hours of life.

Autopsy, forty-eight hours after death. Body extremely emaciated and exsanguinated, though a considerable thickness of fat still remained over the abdominal walls. On dividing the skin and subcutaneous fat over the spinous processes of the dorsal vertebræ, and especially on lifting the muscles from the sides of these processes, a sinus was discovered extending upward from one of the opened abscesses five and one-half inches along the course of the spinal column. In the neighboring deep muscles there were many minute abscess formations, but no other sinus than the one indicated. Surrounding the dura mater there was a mass about three and two-thirds millimetres in thickness, extending from the point of the opening of the sinus to the tenth dorsal vertebra. The color, appearance, and general condition of the dura mater, the pia mater, and the cord were perfectly normal, except that the latter exhibited evidences of having undergone compression, but not to such an extent as to indicate even a commencing condition of myelitis. Between the muscles and large nerve-trunks the loose tissue showed an acute inflammatory process.

That this case evidenced peripachymeningitis spinalis rather than simple spinal meningitis had been shown during life from the conspicuous absence of some of the leading symptoms of the last-named disease, notably cephalalgia, spinal rigidity, and reflex excitability. The autopsy sustained this view.

The facts in the case which are of an especial interest relate to the course of the disease, and in such relation mark it as rare. Although impossible to determine the precise etiological connection between the two trains of circumstances, it is quite evident that in the first instance the meningeal inflammation and consequent spinal hemiplegia were secondary to the action of muscular in flammation, and that in the second instance this was precisely reversed. The inflammation in the external tissues was an incident that antedated the spinal affection; but the discharge of a piece of bone from the fistula, that was discovered post mortem, is in the way of evidence, in connection with other clinical events, to point to an origin of apparently primary spinal affection. This, however, is not positively certain.

The Question of Priority in Circumcision under Cocaine.—Dr. W. C. Fisher, of Galveston, Texas, writes: "Dr. B. F. Kingsley, of San Antonio, Tex., refers, in a recent number of The Medical Record, to a case reported some time since by Dr. E. R. Palmer, and says that he operated on November 29, 1885, and makes the claim to priority in the use of cocaine in circumcision. I have no desire whatever to take the wind out of the doctor's sails, but if he will refer to the November number of the *Texas Courier-Record*, page 98, he will find an article entitled, 'A Few Clinical Observations on the Use of Cocaine in Circumcision and Ablation of the Toe-Nail.' By reference to my notes I find that the cases reported were operated on on the following dates: First, April 3, 1885; second, May 18, 1885; third, May 25, 1885; fourth, July 20, 1885; fifth, July 20, 1885; sixth, July 23, 1885; seventh, August 3, 1885. Since the report of these cases I have performed a good many more circumcisions under cocaine, and generally with good results. Intead of a rubber bandage, I find that a simple rubber band, such as we use around a pocket-book, answers every purpose. I do not claim that I was the first to use cocaine in circumcision, for I believe two other gentlemen used it once or twice before I did."

An Easy Labor.—Dr. S. C. Bridgwater, of Dixon Springs, Tenn., writes that not long ago a negro woman was walking along one of the streets of that town, when suddenly labor pains began, and before she could get out of town she gave birth to a large, healthy child. She picked up the baby, and carried it in her apron about half a mile to her home. She had no medical attendance during or after the labor, and both mother and child did well.

Progress of Medical Science.

Mammary Abscess.—Dr. Bumm has recently made suppurative inflammation of the mammary glands the subject of special inquiry, and has published his views in No. 282 of *Volkmann's Sammlung Klinischer Vorträge*. A good *résumé* of these views is found in an editorial article in the *Philadelphia Medical Times* of October 16, 1886. Dr. Bumm points out the fact that the frequency of the mammary abscess is so much greater during the periods of functional activity of the glands, that it may be practically regarded as a disease of lactation. He refers cases of this affection, as it occurs in lying-in and nursing women, and occasionally also during pregnancy, to two groups, differing in causation as well as in their course and termination: 1, Simple parenchymatous (non-infectious), and 2, phlegmonous (infectious) mastitis. 1. Simple or non-infectious mastitis is due to the accumulation and retention of the newly formed secretion, and differs in degree only from that physiological fulness and tension which are felt in the breasts upon the second or third day after parturition. The mammæ, being but poorly supplied with intrinsic contractile elements, and wholly lacking the influence of extrinsic muscles, are less favorably arranged than the other glands of the body for the discharge of their secretions. They are dependent upon the aid of the suckling or, in its absence, of the breast-pump. If this aid be deficient, the retention which follows may cause local and general disturbances that are, especially in women of irritable, nervous organization, of some moment. The temperature may reach 102.8° to 104° F.; the breast is full, hard, and painful; red streaks extending in the direction of the axilla may indicate inflammation of the lymphatics. But the tendency after massage and suction is to dispersion and resolution, and only exceptionally is there necessity for evacuation by an incision through the skin. Even then the discharge is not pus, but milk in process of inspissation and disintegration of the globules, and, with the rare exceptions, it is free from bacteria. Here we have the familiar "weed" of the old nurses. 2. But in phlegmonous or infective mastitis we have a very different and much more troublesome affection to deal with. The line of separation between the two conditions is sharply defined. In fact, they have nothing in common, except the same anatomical seat, nor can there be any question as to the development of the graver out of the milder malady. Phlegmonous mastitis occurs more than twice as frequently in primiparæ as in multiparæ; much more frequently in women who are nursing than in those who are not. It begins, in by far the greater number of cases, in the course of the first month after accouchement; lesions of the nipple usually precede it; and, finally, a part only of the breast is commonly implicated at first, and that part is usually the undermost, or the under and outer part. Errors in diet, colds, worry, mechanical irritation, are, singly or together, quite incapable of causing this form of inflammation. It is due to the presence of specific pyogenic microbes. These cocci are found, sometimes arranged in clusters (staphylococci), sometimes in chains (streptococci), and are to be distinguished from other microbes of similar form by the peculiar appearance of their pure culture and by their active growth, while the energy with which they take up and retain aniline dyes renders their study in the tissues comparatively easy. The distribution of these organisms is so wide and abundant that their contact with the nipples is almost unavoidable. Any want of the most thorough cleanliness, any abrasion, maceration, or loss of epithelium, opens the way for the infection of the deeper structures of the breasts. And it is here that the long-recognized relation between lesions of the nipple and phlegmon of the breast finds its explanation. The disproportionate frequency of the latter affection in primiparæ is also made clear when we consider their greater obvious liability to nipple-lesions. The invasion may be subcutaneous, and, by way of the lymph-vessels, deeply into the interstitial connective tissue of the gland, or much more commonly it is by way of the milk-ducts directly into the parenchyma. Infection once set up, milk-retention, by widening the ways of access to the deeper parts, favors the extension of the pyogenic inflammation. The positive knowledge of the etiology and true pathology of phlegmonous mastitis gained by bacteriological studies has less bearing perhaps upon the treatment, which must still be conducted in accordance with accepted surgical procedures, than upon prophylaxis. The hardening of the surface of the nipples by daily bathing with cold water and gentle frictions during the later months of pregnancy, and their systematic bathing after nursing, long advised by cautious midwives, have now more than a mere empirical basis. To avoid all maceration, and guard them by vaseline or oil, while yet sound, and to heal without delay each fissure or abrasion so soon as it appears, are measures no longer to be lightly neglected. "Sore" or "cracked" nipples are troublesome enough in themselves: in the light of their relation to "gathered breast" they acquire a new and serious importance.

An Overdose of Cocaine.—Grave symptoms due to acute intoxication from the hypodermatic use of cocaine have not hitherto been frequently observed. Dr. Ramsden places on record, in the *Australian Medical Gazette*, the following case: B. C—— had been suffering from neuralgia caused by a defective tooth. It was decided to extract the offending tooth. This was found to be impracticable and an injection of cocaine (ten per cent. solution) was then given. The patient found immediate relief, lasting a number of hours. Dr. Ramsden then continues as follows: "Next day, the pain being very severe, he sent to his chemist for a similar solution, and had three minims injected, but without the desired effect; he returned it to the chemist and asked him "to make it stronger," which he did, making it twenty per cent. He brought this to me, but omitted to tell me that the solution was double the strength of that which I had used. He told me that three minims had not given him the relief that he had experienced from mine; I therefore gave him four minims of what I believed to be a ten per cent. solution, and within five minutes he became restless and inclined to vomit; he then began to feel a sensation of pins and needles in the left hand and arm, which rapidly extended to the right side. This was speedily followed by contraction and rigidlty of the fingers, arms, and legs; there was also a tendency to opisthotonus. His pulse became extremely rapid and feeble, his face livid, and the muscles of his mouth and cheeks strongly contracted. His respirations were short and convulsive, his feet and hands very shortly became cold, and a profuse perspiration broke out on his head and face. I first gave him half a tumbler of brandy, followed at short intervals by drachm doses of spiritus ammoniæ aromatici, and applied strong mustard over the cardiac region, and used friction to the upper and lower extremities; at the same time I let him inhale a few drops of chloroform to try and check the spasmodic contractions. After continuing these remedies for nearly an hour the pulse began to improve, the color to return to the face, and the rigidity of the muscles lessened, but returned again immediately I stopped the friction. At the end of two hours he improved more rapidly, but felt somewhat drowsy, and it was not until about four or five hours that all the symptoms had subsided. On questioning him afterward regarding his sensations, he told me that although he was unable to speak coherently he knew all that was passing, and it was not until he felt the abdominal muscles becoming rigid that he felt anxious, for then he thought he was dying, and a sensation of suffocation came over him."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 1, 1887.

ARSENIC IN SKIN DISEASES.

IN July last the editor of the *Journal of Cutaneous and Venereal Diseases*, through the pages of his own and other medical journals, requested information from physicians in relation to the general practice of employing arsenic in skin diseases, its superior value to other remedies in this class of affections, its ill effects, the preparations of the drug preferred, the doses employed, etc.

In response to these inquiries about seventy communications were received. The information contained in many of them was so meagre and indefinite as to be practically valueless. Many of the correspondents were non-committal, or expressed themselves in such general terms that their real opinions upon the points specified were largely conjectural. An analysis of the letters in which the answers were for the most part categorical, and contained definitely expressed views, based upon personal experience, shows the following result :

In answer to the question, "Are you in the habit of employing arsenic *generally* in the treatment of diseases of the skin?" in over sixty per cent. the answer was "Yes," in some cases qualified by the terms "largely," "continuously," "almost exclusively," in "all scaly diseases," etc. In two or three cases it was emphasized, one correspondent declaring that he used arsenic in all cutaneous diseases non-syphilitic in origin ; another, still more enthusiastic, proclaims that his practice is to give arsenic "*not only generally*," "*but invariably in every case.*" Only ten correspondents give an unqualified "*No*" to the question. A number state that they formerly used it extensively, but now have little faith in it.

From the answers to the second question, "In what forms of skin disease have you found arsenic of superior value to other remedies?" it would appear that the superior virtues of this drug shine forth most brilliantly in a large range of skin affections. The diseases enumerated are alopecia simplex, alopecia areata, acne, atrophy of nails, erythema, eczema papulosum and squamosum, psoriasis, pityriasis capitis, crusta lactea, lichen agrius, lichen ruber, urticaria acute and chronic, furuncolous, herpes zoster, pemphigus, purpura, vitiligo, strophulus, prurigo, impetigo, herpes, scabies, ambustio, gelatio, various syphilodermata, and certain other diseases not recognized in the nomenclature adopted by the New York Dermatological Society. Others, instead of particularizing diseases, extol its superior value in "all scaly diseases," "in all chronic cutaneous troubles ;" another "in anæmias and morbid conditions of the cutaneous glands ;" still another, in all cases where there is exudation, with infiltration into the cutis vera. The homœopathic proclivities of one correspondent are disclosed in the statement that "arsenic is of superior value in all diseases indicated by the similarity of the symptoms." One correspondent somewhat scornfully repudiates the idea of a comparative estimate of the value of arsenic with other drugs. He says: "I cannot compare it with other drugs, as I never use anything but arsenic."

The third question, "What ill effects, if any, have you observed from its use?" is passed over in silence by many of the correspondents. Eighteen declare they have seen none; nineteen have observed nausea, stomachal and conjunctival troubles. Many testify that arsenic frequently aggravates cutaneous inflammation.

One correspondent states that of 197 cases treated by arsenic, there was a rebellious eruption in ten per cent. ; in twenty per cent. it produced puffiness of the face and a dryness of the fauces. In one case it produced urticaria; in another erythema; in three it aggravated eczema.

To the fourth question, "What preparation of the drug do you prefer, and in what doses do you employ it?" the answers would indicate that there is a pretty general uniformity of practice in the employment of Fowler's solution—dose, one to twenty drachms three times a day. Some prefer Donovan's solution (same doses), arseniate of sodium; others arsenious acid, one-sixtieth to one-sixth grain, iodide of arsenic, bromide of arsenic, etc.

As an illustration of the variety of preparations open to the choice of the ambitious arsenicalist, I quote here the arsenical armamentarium of one correspondent : "The preparations I use are arseniate of potash, arseniate of soda, arseniate of ammonia, arseniate of quinine, Fowler's solution, Donovan's solution, De Valangin's solution, iodide of arsenic," etc.

In submitting an analysis of these communications, which embody for the most part the results of the experience of general practitioners, we are aware that there may be a question as to their practical utility. There are many circumstances, unnecessary to detail here, which detract from their positive value as a contribution to our knowledge of the subject. They certainly seem to sustain the proposition enunciated by Dr. Fox, that it is the practice of many physicians to give arsenic in nearly any case of skin disease, the truth of which assumption was challenged by some of the members of the Dermatological society at the informal discussion at its June meeting. They also establish the fact that many physicians, who formerly employed arsenic generally or indiscriminately in skin diseases, have lost faith in the drug, and now employ it only in a limited range of diseases. From this it may not be unfair to draw the conclusion that, in proportion to the widening of our knowledge and the broadening of our experience, the use of arsenic is restricted in the treatment of skin diseases.

Another point of interest is the fact that the incidental effects of the drug upon the skin occur in a notable proportion of all cases in which it is used. Quite a number of correspondents refer to its effect of increasing

cutaneous inflammation, and the production of various forms of eruptive disturbance.

The experience of Dr. Faithful, of Australia, upon this point may be quoted entire. He observed intense itching all over the body, coming on principally when the patients get into bed, with dryness of the skin and furfuraceous desquamation. In one case, herpes preputialis, which always made its appearance after giving arsenic for a few days, minim doses of Fowler's solution or liq. arsenici hydrochlorici (Br. Ph.) producing it almost as rapidly as five-minim doses given three times a day. In another case a papular eruption about the face attended with a decided amount of pruritus. The papules varied in size from a pin-point to that of a No. 4 shot, were discrete, and were more or less scaly upon the summit. The eruption disappeared after a few days upon the discontinuance of the drug, and was followed by furfuraceous desquamation of the parts affected.

PNEUMONIA AND PNEUMOCOCCI.

The science of bacteriology is yet in its infancy, and though enthusiasts are not wanting who claim that specific microbes have been discovered for nearly every disease; from cholera to bromidrosis, it can hardly be said that the specificity of any micro-organism, with the possible exception of the tubercle bacillus, has been established with absolute certainty. Some investigator will find a certain species of microbe in every case of a certain disease, and may even be able to produce apparently the same disease by inoculations of pure cultures of this microbe. He then proclaims to the world that he has discovered the specific micro-organism of this disease, and perhaps busies himself in a search after some substance which will kill the micro-organism without at the same time destroying its host. But soon another investigator appears who has found some other microbe in the same disease, and is equally certain that this is the true microbe of the disease, and that the other investigator was mistaken.

Even the pneumococcus of Friedlander, if we may trust some recent experiments of Drs. Palamidessi and Modigliano, reported in the *Rivista Internazionale di Medicina e Chirurgia* for November, 1886, is not constant in its relations of cause or accompaniment of pneumonia. These investigators have examined the sputa and the pulmonary tissue in numerous cases of pneumonia occurring in Pisa during the winter of 1885–86, and have found a micro-organism, it is true, but not the so-called pneumococcus. The microbe found by them differed in all its characteristics from the pneumococcus described by Friedlander, yet in experiments upon animals with pure cultures they were able to excite a disease possessing all the pathological appearances of pneumonia. There was always a fibrinous exudation at the seat of the injection, and the tissues, when examined later, showed an abundant infiltration with the identical micro-organisms.

They conclude, as a result of these experiments, that:

1. There may be cases of pleurisy and of pneumonia in which the diplococcus described by Friedlander is absent.

2. These cases of pleurisy and pneumonia are produced by another variety of micrococcus.

3. This micrococcus differs wholly from those forms hitherto found in these diseases.

It would therefore seem that Friedlander was mistaken, or Palamidessi and Modigliano were mistaken; or that there are varieties of pneumonia which cannot be distinguished from each other clinically; or, finally, that the specific microbe of pneumonia, if any exist, has not yet been discovered. But perhaps it is the safest to assume that bacteriology has not yet attained the level of a certain science.

THE SIGNIFICANCE OF ABSENCE OF HYDROCHLORIC ACID IN THE DIAGNOSIS OF GASTRIC DISORDERS.

Of late years several writers, chiefly in Germany, have called attention to the frequent absence of free hydrochloric acid in the contents of the stomach in carcinoma of that organ, and some have even maintained that such absence is pathognomonic of that affection. Van den Velden was among the first to note this sign, and he was also inclined to attribute to it greater diagnostic significance than were later workers in the same field. He believed that it was symptomatic not only of cancer of the stomach but of cancer in general, and asserted that it was possible to determine whether any given tumor were benign or not by the presence or absence of free hydrochloric acid in the gastric secretions. Schiller, Seemann, Kredel, Riegel, Hübner, and others have come to the same conclusions as regards carcinoma of the stomach, though their researches have shown that the absence of free hydrochloric acid is by no means constant in cancer of other organs, and, indeed, Hübner ventured in one case of cancer of the peritoneum to exclude disease of the stomach, because he found hydrochloric acid present in the contents of that organ. Riegel also asserts that the presence of this acid is sufficient evidence of the non-existence of carcinoma of the stomach, and that if, on repeated examinations, its absence is definitely determined the diagnosis of cancer may be made with safety.

These results, however, are by no means confirmed by other observers. Ewald found hydrochloric acid in the contents of the stomach, in 13 out of 23 cases of cancer of this organ, though in a later series of 7 cases he found free acid present only once, and that in a doubtful case. Golding Bird found a large amount in the fluid vomited in a case of scirrhus of the pylorus, although later in the disease the acid nearly disappeared.

Dr. Luigi Sansoni has recently made a number of observations in this direction (*Rivista Clinica*, No. 10, 1886), the results of which are not devoid of interest. He examined the contents of the stomach in four cases of cancer at different periods, before and after the ingestion of food, and was unable at any time to find any traces of free hydrochloric acid. He made in all 86 analyses of the gastric secretions in 35 individuals, and noticed the curious fact that in men hydrochloric acid was always present, except in those suffering from carcinoma, while in women it was frequently absent. Of 61 analyses made in 27 women, hydrochloric acid was absent fifty times. Of these analyses, the larger number

(36) were in hysterical women, and only once was free acid found, and then only in very small quantity. He thought that this absence might justly be attributed to nervous disturbances, and instanced in support of this view the alterations in other secretions, such as the sweat, urine, saliva, etc., as often observed in hysterical women. The absence of free acid in other, non-hysterical, women might be attributed to the sedentary lives which they lead. By reason of the small amount of exercise which they take, the food remains longer in the stomach, and the albuminous solutions, peptones, etc., seize upon the acid, so that it is no longer free and fails to give the characteristic reactions.

As a result of his observations the author concludes that a chemical analysis of the contents of the stomach is often of great value in the diagnosis of gastric disorders, and that, while the absence of free hydrochloric acid is by no means pathognomonic of carcinoma of the stomach, still less of cancer of other organs, it is, nevertheless, taken in connection with other symptoms, a sign of much importance and one which goes far to establish the diagnosis of cancer in doubtful cases.

FATTY HEART.

Probably no disease sounds by name to the laity more terrible than fatty heart. That it is a well-recognized clinical condition, no one doubts. That physicians use the expression somewhat carelessly, is none the less true. It is possible for a person to have a fatty condition of the cardiac muscle and yet completely recover, as far as we can judge from his subsequent history. The expression —fatty heart—is one which should not be used carelessly by medical attendants. Often patients get wrong and distorted ideas of their own maladies, and are thrown into a condition of despair and anxiety, from which they might easily have been free.

In a recent issue of the *Edinburgh Medical Review*, Dr. Milner Fothergill makes a sensible protest against the indiscriminate use of the term under discussion, and shows conclusively how a process, generally pathological, may be, under certain conditions, almost normal, and far from conveying an inference of permanent structural damage. In the uterus of the puerperal woman the process of fatty degeneration is the one by which the organ is restored to its normal state. After a continued fever the heart itself shows evidence of fatty changes, but they are only temporary. With the return of health these cardiac changes disappear, and the normal tonicity of the organ is restored. So also in anæmia, similar changes result. The heart-walls are weakened and the valvular orifices relaxed. There results a temporary incompetence at the valves, and another cause of murmurs is added to that of the watery condition of the blood. A proper course of tonic treatment removes all this. Repeated hemorrhages induce the same condition, which is produced also artificially in animals by repeated venesection.

All these facts go to show that the condition of fatty heart is not necessarily an incurable or positively dangerous one. This latter element must be determined by the causative factors. Patients are told they have fatty heart, and this statement they often regard as their death-warrant. They live, however, to disprove the prognosis of their advisers. If there are other signs of cardiac trouble—changes in vessel-walls, evidences of imperfect circulatory changes, and so on—then the prognosis is grave indeed. But we should not apply the term "fatty heart" indiscriminately, with its general clinical significance, to all those conditions where there may be but slight cardiac changes.

THE HISTORY OF MASSAGE.

A recent work has for its title the "History of Massage." Its author is Dr. Hünerfauth, of Homberg. Its salient features have been rendered accessible to English readers by a contribution to the *Nineteenth Century* from the pen of a woman—Lady John Manners. We learn that the word "massage" comes from a Greek word, meaning to rub, or more directly from an Arabic term "mass," that is, to press softly. There is trustworthy evidence to show that the process was known to the ancients, and was practised by them as a therapeutic measure. It has long formed a part of the hygienic gymnastics of the natives of India. "Before the Indians begin their exercises, they cower on the earth and by turns rub each other with the mud from the delta of the Ganges when they can obtain it. All the muscles of their bodies are pressed and kneaded. When Indians are unwell, they frequently employ a cure called 'chamboning;' the whole of the patient's body is gently kneaded, beginning with the upper extremities, and descending to the feet."

Records of travellers show that it is practised in nearly all the islands of the Indian and Pacific Oceans. At the Sandwich Islands it is known as Lomi-Lomi, and the operators are usually old women. A massage treatment is the highest honor a host can extend to his guest, or receive from him. It is sometimes the custom for the natives, when greatly fatigued, to lie flat on the ground and allow little children with feet bared to walk over their backs.

In the older classical nations, where bodily perfection was such a high aim, the application of the principles of massage was made the chief feature in all physical exercises. Passing through the history of the earlier centuries of the present era, we find that in 1708 Hoffman laid the foundations of the present gymnastic exercises of the German schools. Half a century later Tronchin, at Paris, made a great reputation by his prescribing massage exercises. About 1805 Peter Ling established in Sweden the basis of the present Swedish "movement cures," which constitute one of the most popular forms of massage. Various mechanical appliances are used in the latter system. These appliances our author, Dr. Hünerfauth, regards as injurious because too violent.

But it is only of late years that this new-old remedy has been reduced to a system. Now its benefits are universally acknowledged. Its limitations are fully recognized. Lady Manners, in her interesting article, makes the pertinent suggestion that the practice of massage would afford an outlet for many unemployed women. It is true that the general principles of the practice are included in our training-school courses. But many women might become successful manipulators

who would not be qualified for professional nursing. In these days, when so much is being said and written about employment for women, the suggestion is certainly worthy of remembrance. Physical strength is a first requisite, and hence the number of applicants for this new service would limit itself. The establishment of an institution for the systematic treatment of massage might not be a bad idea.

A SURGEON'S SUICIDE AND THE DOSE OF COCAINE.

NOTHING more tragic, and yet interesting in its details, has occurred in the medical world of late than the suicide of Professor Kolomnin. We have already referred to the main facts, but the whole sad history has been recently laid before the St. Petersburg Society of Medical Practitioners, by Professor Botkin, a personal friend of the deceased. It seems that a young woman, aged twenty-three, was sent to Professor Kolomnin, and found to have a large ulcer of the rectum, which was diagnosticated to be of tuberculous nature. He decided to scrape and cauterize the lesion, and to use cocaine anæsthesia during the operation. The details are given by Professor Botkin as follows:

"In order to produce anæsthesia he had fifty grammes of a five per cent. solution of hydrochlorate of cocaine prepared; of this thirty grammes were brought into use, containing exactly twenty-four Russian grains of the salt, or twenty-three English grains [the Russian grain is exactly one-sixteenth of a gramme], six grains being injected at a time into the rectum. After the third of these injections it was found on examination that the part was still sensitive. A speculum was then introduced, the ulcer dabbed with a dry sponge, and then the fourth injection given, making twenty-four grains in all. After this the parts were tolerably anæsthetic. The ulcer was scraped, and a tampon saturated with oil inserted. The pulse was then accelerated. During the operation the patient groaned, so that even the twenty-four grains had not produced complete anæsthesia.

"After the operation Sergei Petrovich (Kolomnin) went round his ward, and in three-quarters of an hour a message was sent to him that the patient was very low. He found the pulse very weak, the face and hands cyanotic, and the respiration labored. He considered that she was in a toxic state, and used every means to bring her round, Professor Sushchinski being also invited to a consultation. Faradization, artificial respiration, hypodermatic injection of ether, administration of ammonia, tracheotomy for the inhalation of oxygen, stimulating and nutrient enemata—all were tried, but without success. Sergei Petrovich (Kolomnin) had no doubt that death was due to cocaine. To what extent was he to be blamed for introducing so large a dose as twenty-four grains into the body? Some time before the operation he asked Professor Sushchinski about the dose of cocaine, and he told him that he considered two grains as the maximum. He, however, collected a number of special papers on the subject in which some thirty cases of cocaine anæsthesia were reported where from six to eighty, and even ninety, grains had been administered. Most of them were cases of lithotripsy. Of course he knew that the bladder, when healthy, cannot absorb such a quantity of cocaine, but some cases of diseased bladder were mentioned where there must have been absorption. Finally, Dieulafoy had performed an operation similar to Kolomnin's, introducing into the rectum forty-eight grains all at once, with complete success, and this served as a guide. He, however, observed additional precautions, employing only half the quantity, and introducing it in divided doses. How far was he to blame? He certainly put too much faith in Dieulafoy's case, but anyone else might have done the same. . . . It is difficult to account for the French surgeon's success. It is indeed possible that, as his operation was performed at a time when cocaine was dearer than gold itself, being two shillings a grain, it may have been adulterated, and therefore the proper effect was not produced. At all events, whatever blame is due to Sergei Petrovich is greatly lessened by the records in medical literature. He himself, besides, said that he was not to blame regarding the operation, but only with reference to his therapeutics. 'I blame myself,' he said, 'most of all for making an incorrect diagnosis; the diagnosis of tubercle was not confirmed. I ought not to have operated at all, and the patient would have been still living. In spite of my not being to blame, I cannot help feeling at times that I killed her.'"

Professor Botkin thinks that Kolomnin was not in his right mind when he killed himself. He had always been a very reserved man, having no intimates, and confining himself entirely to his scientific work. This characteristic was increasing yearly. He was very strict, both with others and himself; very sensitive, no doubt morbidly so.

His use of so large an amount of cocaine was, no doubt, an error of judgment, and his attempt to use cocaine in an operation about the rectum and anus, a locality so difficult to make anæsthetic, was, no doubt, another mistake.

The experience, though so sad, may not be without its lesson. Are there not other surgeons who could report very serious if not fatal results from the injudiciously or ignorantly using too large a dose of cocaine?

BERI-BERI IN NEW YORK.

SEVERAL cases of beri-beri have been observed recently in New York. They were brought to the city on a vessel from San Francisco, nearly all the crew being attacked with the disease, and several dying. Most of the survivors were in a crippled state, and three were taken to Bellevue Hospital, where two died. Unfortunately the disease was not recognized at first, and no examination of the nerves, or the blood, and no culture-experiments were made.

Beri-beri shows itself in a dry, a wet, and mixed forms, and is sometimes acute, but oftener subacute or chronic in its course.

The cases recently brought to the city were of the wet form and chronic in character.

Drs. Cornelissen and Sugenoya, the one a Danish, the other a Japanese physician, living in Java, have shown that the micro-organism which causes beri-beri is very

similar to the anthrax bacillus. It is colored with fuchsin or gentian violet, and easily seen. It is found in the blood, muscles, nerves, and serous fluids.

THE DEATH OF THE LATE GENERAL LOGAN.

The case of the late General Logan appears to be one of those rare ones in which acute rheumatism causes a rapid and fatal issue. On December 12th Dr. J. H. Baxter, of Washington, D. C., was called to see him, and found him suffering from acute rheumatism, involving the right wrist. He improved until the 17th, when he had a relapse, the hips, ankles, feet, and both wrists becoming involved. Brain symptoms also appeared at this time. Though there was some temporary improvement on the 21st and 22d, the symptoms on the whole became gradually more severe, the intervals of full consciousness shorter, until early on the morning of December 26th, when he became comatose. He died twelve hours later.

The cerebral symptoms were those of congestion of the brain.

Acute rheumatism is so rarely a cause of death that some complication is expected, and almost always found, in fatal cases. When death does occur it is, as a rule, with cerebral symptoms, as was the case with Senator Logan. Such symptoms are much more liable to develop in persons whose nervous system has been subjected to tremendous strains, as well as to the toxic effects of narcotics and stimulants.

No doubt the exhausting political and literary labors of the deceased had made it possible for the rheumatic poison to attack and paralyze his nervous centres, thus bringing to a fatal issue a disease that in ninety-seven per cent. of cases is perfectly free from danger to life.

MEDICAL SECTS AND CLINICAL INSTRUCTION IN PUBLIC HOSPITALS.

An interesting article with the foregoing title appeared in a recent number of the *Boston Medical and Surgical Journal*. The homœopathists of that city petitioned the managers of the City Hospital for equal privileges in that institution with the regulars. The trustees considered the request with great fairness, and deliberated long and carefully before making an answer. Circulars were sent out to all institutions where physicians and surgeons of both schools were supposed to be on the attending staff, to learn the practical workings of this arrangement in other places. This dual arrangement was found to exist in only two institutions, so far as answers were received. And in these two instances it was by no means satisfactory. Thereupon the trustees replied to the petitioners that the granting of the request would necessitate radical changes in the management of the hospital.

Three possible plans suggested themselves. Homœopathic practitioners might be added to the attending staff with a full share in all the latter's rights and privileges. Certain wards in the present buildings might be placed under the control of the petitioners, or new wards might be constructed for them. The trustees were not empowered to make such a radical change in management, as the adoption of these latter plans would necessitate. The petitioners were, therefore, courteously referred to the proper authorities, namely the city council.

In regard to clinical instruction, it was decided that the attending surgeons might operate before the students in the amphitheatre on certain days, and that all physicians and all matriculants of one year's standing, at a legally established medical college, might be admitted. This rule was held to apply to female students. The operator might, if he chose, request the withdrawal of students of either sex in certain cases requiring exposure. No male visiting students were to be allowed to witness any operations on female patients requiring exposure of the genitalia. Students, not exceeding twenty in number, might accompany a member of the staff in his daily rounds.

These resolutions are sensible and discreet. Here, in New York, however, the matter seems to have settled itself in substantially the same way without the formality of trustees' decision. We may be pardoned for saying that our own hospitals are more freely thrown open to students and practitioners than seems to be the case in our sister city. Certainly more freedom is allowed the recent graduates, who generally compose the resident staff. Anyone who wishes to attend surgical clinics is not required to show a certificate of matriculation or of professional standing. We have never heard of any abuse of these privileges. In regard to operations on the female genitals, we are even more liberal than our neighbors, for students are regularly admitted by sections to the operative clinics at the Woman's Hospital, and other institutions as well, and everything is conducted with the utmost decorum. This whole subject bears directly, we think, upon the much-discussed question of higher medical education. This is to be brought about, not only by requiring a higher grade of scholarship, but also by giving students greater practical advantages. We are happy to observe that the position from our hospitals in this respect is such a liberal one.

PEPTONURIA.

The term peptonuria has not yet gained a place in text-books, and its clinical significance or practical importance has not yet been satisfactorily defined. Clinicians and urinologists, however, are steadily accumulating data regarding the subject, and it will not be long before dogmatic teachers will have to introduce it into their courses. Frerichs in 1851, and Mahle in 1852, first noticed that peptone, or, as the latter then called it, albuminon, is not infrequently found in the urine. Frerichs found it in a case of acute yellow atrophy of the liver; later Gerhardt and Schultzen and Ries found it in acute phosphorous poisoning, and in other conditions attended with acute destruction of the liver. Hoffmeister in 1879 showed that peptonuria occurs in other diseases, and especially in acute suppurative processes. Basing his reasoning on Hoffmeister's observations, Von Jaksch diagnosticated a rupture of the sac and suppuration in a case of ovarian tumor.

Fenomenon found peptone in the urine in cases of excessive formation of young cells along the genito-urinary tract.

Maixner, Bouchard, and Sée have found peptone in the urine in various gastro-intestinal disorders; *e.g.*, can-

cer, catarrh of the stomach and intestines, gastro-ectasis; also in typhoid fever, and in tuberculous and waxy degenerations of the intestines.

Wassermann and Hoffmeister have shown that peptonuria may occur, not only in acute phlegmasia, but in those cases in which there is a profuse serous exudation, as in acute pleurisy and pericarditis.

Jaksch found peptone in the urine in three out of seven cases of scurvy. Peptonuria occurs sometimes in cases of pernicious anæmia. It occurs not only in acute yellow atrophy of the liver, but in one-third of the cases of fatty enlargement of that organ. Senator and Petri say that there is always some peptone in albuminous urine. Poehl, however, denies this, and says that it is only found when albuminous urine is acid. The facts appear to be that in the severe albuminuria of nephritis there is no true peptonuria, but that it may occur in unlike types of albuminuria, and is then due to a transformation of the albumen (Bouchard). In other words, peptonuria accompanying albuminuria has no significance. In dilation of the stomach peptonuria has been observed in sixteen per cent. of (371) cases.

Peptone is a hydrated albumen, which normally, in passing from the gastro-intestinal tract, is mostly dehydrated, becoming the serum and albumen of the blood. Some of it appears to be taken up by the white blood-cells; and when these are multiplied or broken up, as in acute suppurative processes, or scorbutic and septic affections, the peptone is discharged, and passes away by the kidneys. In gastro-intestinal maladies, it is possible that the peptone is not all dehydrated in its passage into the blood, and hence peptone reaches that fluid and circulates with it.

Peptonuria is thus classed by Bouchard as gastro-enterogenous, hepatogenous, hæmatogenous, and phlegmasic. Looked at from another point of view (Ultzmann), it may be said to be present in three conditions: one a general one, including scurvy, typhoid, diphtheria, tertiary syphilis, pernicious anaemia, small-pox, cerebro-spinal fever, phosphorous poisoning, in which it seems to be connected with a general disorganization of leucocytes; the second, a local condition, including pleurisy, croupous pneumonia, pericarditis, acute inflammatory rheumatism, in which it is connected with absorption of exudates rich in leucocytes; the third, also a local condition, including gastro-intestinal diseases associated with imperfect absorption and dehydration of peptone.

It also occurs from local causes in nephritis and genito-urinary catarrh.

Peptonuria does not occur in large amount in the urine. The best of ordinary tests is, perhaps, prussic acid with heat and cold. Prussic acid precipitates peptones; but the fluid if heated clears up, and then is clouded with peptone again on immersion of the test-tube in cold water.

FREE DISPENSARY FOR DISEASES OF THE LITTLE TOE.

The Hospital publishes the full account of how a young medical man, rather anxious for something to do, and Mr. Jeremy Diddler, who is a sort of professional hospital organizer, devised a scheme for establishing "a dispensary for diseases of the little toe." The circular which Mr. Diddler concocts is such an excellent travesty on the current methods of "booming" a new charity that we publish it in full.

FREE DISPENSARY FOR DISEASES OF THE LITTLE TOE.

—— Street, —— Square.

In the year of 1883, 30,807 persons died of diseases of the little toe. This number (which includes cases of gangrene, pyæmia, phlebitis, and bunion) is exclusive of the very numerous deaths from wasting diseases and cancer of the digit. (See *Registrar-General's Report.*)

According to the above extract, diseases of the little toe have occasioned more deaths in England than diseases of any other organ, and a comparison of the returns for 1883 with those of the previous years shows that these diseases are increasing in a ratio greatly out of proportion to the increasing population.

Deaths from Diseases of the Little Toe.

Year.		Year.		Year.	
1874.....	13,846	1877.....	17,908	1880.....	21,915
1875.....	15,401	1878.....	19,634	1881.....	30,940
1876	15,009	1879.....	20,879	1882.....	24,802

1883.....30,807

Besides the above number of fatal cases, there is a still greater number of diseases of the little toe not terminating in death, but which give rise to extreme suffering and misery, especially among the poorer classes. *This is the only institution specially devoted to the treatment of diseases of the little toe*, and the fact that in less than two years upward of 10,560 patients (from all parts of England) have been relieved, proves that it is a necessity. The employment of the newly invented instrument (the little-toe scalpel) is a special feature in the institution, and by the aid of this instrument morbid conditions of the digit can be fully exposed and adequately treated. Further aid is required to meet the urgent demands caused by the daily increasing number of out-patients. It is likewise essential that a ward should be speedily opened for the reception of the more acute cases. *At least £1,000 is required to establish a ward containing six beds.* For this purpose the committee have determined to open a new subscription list. Those who desire to assist in this particular way will please notify that their subscriptions or donations are to go to the "ward fund." The benevolent are respectfully informed that the very existence of the institution will be jeopardized unless the funds are considerably augmented.

JEREMIAH DIDDLER, Secretary.

News of the Week.

THE PARIS ACADEMY OF MEDICINE ON THE ADULERATION OF WINE.—After a long and laborious discussion, the Académie de Médecine has finally delivered itself of something definite upon the above subject. Advising from a hygienic point of view, the academy declares: 1. That the *vinage* or alcoholization of wine by pure alcohol to the extent of two degrees may be permitted, but beyond this it should be absolutely forbidden. 2. The addition of alcohol is not only dangerous by its quantity and by the bad quality which is often used, but also because it leads to the practice of "watering," which is at the same time a fraud and an adulteration. 3. The so-called "higher" alcohols considerably increase the dangers of brandies and liqueurs, and it is reasonable to require that the spirits used for the fabrication of these products should be absolutely pure. 4. The academy calls the attention of the authorities to the necessity of restricting the number of retail drink-shops, and of putting into force the laws for the repression of drunkenness. It would appear that the addition of two degrees of alcohol is necessary for the preservation of certain wines of low strength.

DR. J. H. DOUGLAS has gone South for his health, and will spend his leisure in writing up the medical history of General Grant's case.

Singular Mortality among Miss Hoyt's Medical Experts in the Famous Jesse Hoyt Will Case.—Since Miss Mary Hoyt commenced the contest, in 1883, against the probate of her father's will, five of her medical experts have been placed *hors de combat* by death, and one by insanity. Dr. J. C. Hennan was the first to die; Dr. Frank Hamilton died last August; Dr. T. A. McBride died at sea the first of last September; and Dr. James A. Milne, of Oswego, died recently from an accident. Dr. Tausky has been an inmate of an insane asylum for about two years. The medical witnesses and experts on the side of the executors are all alive.

Mr. T. Bird.—We have received a note from our friend, Dr. J. A. Irwin, protesting against the paragraph in our recent issue referring to Mr. Bird. There was no intention on our part of casting any aspersions upon Mr. Bird, but we merely gave his professional titles and standing as a matter of news.

A Bill to Extirpate Contagious Diseases.—A bill has been introduced into the Senate and House, authorizing the appointment of a commission of three persons, to be charged with the duty of extirpating contagious diseases of animals in this country.

Suicide and Plumbing.—A citizen in St. Louis committed suicide because compelled by the city health department to make proper connections from his house with the sewer.

The Lady Medical seems to run to Nihilism in Russia, as she does to homœopathy in this country. A report says that eighteen female medical students have been expelled from St. Petersburg for taking part in a meeting which had been forbidden by the police. The female medical school has long been considered a nursery of Nihilists, and attempts have been made to close it altogether.

No Limit to the Students of Medicine.—The Vienna professorial body having been asked by the Minister of Education whether it would not be well to place a limit on the number of students of medicine received, has unanimously pronounced against the adoption of any rule of this kind.

Ophthalmoscopy will be Made more Easy, according to M. Giraud-Teulon, when the direct illumination of the fundus by an electric light fixed in the body of the mirror is used instead of reflected light. Dr. Teulon has devised an instrument for the purpose.

The Suprapubic Operation for Stone is the popular one in Europe now.

Abscess of the Brain from Tympanic Suppuration correctly Diagnosticated, Localized, and Successfully Operated Upon.—The first case of this kind on record has recently been reported by Dr. W. R. Gowers and Mr. Arthur E. Barker, in the *British Medical Journal* of December 11th.

Dr. William C. Wile, of Newtown, Conn., editor of the *New England Medical Monthly*, has been elected lecturer on nervous diseases and electro-therapeutics in the faculty of the Medico-Chirurgical College of Philadelphia.

Fernandez on a New Anti-rabies Inoculation.—Dr. Fernandez, of Barcelona, claims to have discovered a new vaccine to preserve men and animals from the contagion of rabies. He has collected a great number of observations, showing that dogs bitten accidentally by vipers are never affected by rabies, either spontaneously or when bitten by affected animals. He has made certain direct experiments, inoculating dogs with a small quantity of the viper's poison. After inoculation the animals were ill for four or five days, with symptoms of slight fever, prostration, and more or less profound somnolence. He maintains that the animals thus operated on are protected from rabies, and that neither when inoculated with the saliva, nor when bitten by affected animals, do they contract the disease.

Preventive Inoculation against Phthisis.—M. Vittorio Cavagius has reported to the Académie des Sciences, November 29th, that a two per cent. solution of carbolic acid destroys the infective power of tuberculous virus, that a weaker solution (1.25 per cent.) enfeebles or attenuates it. By inoculation of rabbits and guinea-pigs first with inert tuberculous matter, then with attenuated, he found that they were not made tuberculous even when pure tuberculous matter was injected.

Deaths from Phthisis.—Dr. Thomas J. Mays, from a study of the vital statistics of several large cities, finds that on the whole the deaths from consumption are less now than formerly, and that the present ratio does not differ greatly in the eastern cities in question. Thus, for Boston it is 15.50 per cent. of the total mortality; in New York (in 1875), 14.09; in Philadelphia, 14.00, in Providence, R. I., 15.43, and in Baltimore, 15.55. In 1885 the ratio was 14.5. Dr. Mays makes a plea for the establishment of a special hospital for consumptives.

Cyanates and Uræmia.—Dr. Walter S. Haines, of Chicago, takes exception to the theory of Dr. Peters concerning the production of uræmic convulsions. The theory is based, he says, upon the misconception that cyanates and cyanides are similar in their physiological action, whereas they are widely separated in this as they are in their chemical and physical properties. He quotes Rabuteau ("Eléments de Toxicologie et de Médecine Légale," p. 77), who concludes, as the results of his own experiments with cyanates: 1. That these salts are not dangerous, at least in the doses in which they were given. 2. That they do not remain unchanged in the organism, but are transformed into carbonates, so that the urine becomes alkaline when they are administered to dogs by the stomach in doses of upward of twenty-three grains. Injected into the veins of a dog, fifteen grains of pure cyanate of sodium produced no effect on the health of the animal. "As the cyanates, therefore, appear to be quite inert, their production and retention in the system could not in the slightest degree explain uræmia and uræmic convulsions, and consequently Dr. Peters' theory, I fear, must fall to the ground along with most, if not all, of the other explanations that have been advanced to account for this condition."

Dr. Josef Moeller, of Vienna, has been appointed by the Emperor professor of pharmacology in the University of Innsbruck.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 6, 1886.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

MALFORMATION OF THE HEART—RUDIMENTARY LUNG.

DR. FRANK FERGUSON, from the Committee on Microscopy, submitted the following report on specimens presented by Dr. J. Lewis Smith, November 10, 1886:

"The material consists of the heart and lungs, a portion of the œsophagus, and trachea.

"The trachea, which appears a trifle small, terminates in a right and left bronchus. The left bronchus, whose size corresponds with the size of the trachea, leads into the left lung. The left lung is greatly distended with blood and air. It measures from apex to base three and one-fourth inches.

"From hilum to free border it measures two and one-half inches. The right bronchus at its origin is the same size as the left, but it soon terminates in a number of very small bronchial tubes which lead into a rudimentary lung, which measures three-fourths of an inch in length, from hilum to free border one-half inch, and is one-eighth of an inch in thickness.

"The œsophagus passes down in its normal relation to the trachea, and is closely related to, and covers in the right lung posteriorly. Anteriorly the right lung is adherent to the pericardium, and covered in by the wall of the right auricle between the ascending and descending venæ cavæ.

"Air has entered into the rudimentary lung, and it is well supplied with blood-vessels.

"Its alveolar walls are thick, and composed of yellow elastic and white fibrous tissue, with numerous spindle-form cells.

"The vascular supply of the rudimentary lung is not traced.

"The heart has one auricle and two ventricles. The right ventricle, with a very thin wall, has a capacity of one-half drachm. A well-developed pulmonary artery extends from it, and enters by one large single branch into the hilum of the right lung. The pulmonary valve is normal in location and structure.

"The right ventricle communicates with the left by an opening, which is not valvular in character, one-eighth of an inch in diameter, and one-half inch below the pulmonary valve. The left ventricle has a capacity of about five drachms. The aorta, arising from the ventricle in the usual location, is moderately dilated. The aortic valve is normal in location and in structure, with a capacity to admit a cylinder one-quarter of an inch in diameter.

"The ductus arteriosus is open, and admits a probe one-sixteenth of an inch in diameter.

"The mitral valve admits a cylinder one-half inch in diameter. It is composed of one continuous curtain of fibrous tissue, from the free edge of which very numerous tendinous cords extend to the fleshy columns of the wall of the left ventricle. The left ventricular wall is considerably hypertrophied.

"The auricle has a capacity of one and one-half ounce.

"There is no attempt at the formation of a septum. The left auricular appendix extends forward in the normal location, and measures one and one-quarter inch in length and one-quarter of an inch in diameter.

"The right auricular appendix is enormously distended, and filled with a firm, dark blood-clot. It is egg-shaped, one and one-half inch in length and one inch in its greatest diameter. The wall of the auricle, everywhere, is thin.

"The pulmonary veins of the left lung converge to form one vein, which empties into the auricle.

"Under the microscope the fibres of the muscular wall of both the ventricles and auricle are seen normal in appearance."

FIBROMA OF THE LOWER JAW.

Dr. Ferguson also reported on the specimen presented, November 24, 1886, by Dr. Wesley M. Carpenter, in behalf of a candidate.

"The tumor is continuous with the periosteum of the jaw-bone anteriorly. There is considerable bone-destruction on either side of the symphysis. The incisors are crowded to either side. Tumor is labulated. It measures antero-posteriorly one and one-half inch; laterally, one and one-quarter; and vertically, three-quarters of an inch.

"Histologically it is a pure fibroma."

DR. T. MITCHELL PRUDDEN presented a beautiful specimen, consisting of the

ARTERIES OF THE ENTIRE BRAIN,

obtained by maceration and washing. Nearly all the arteries had been affected by chronic endarteritis, and the same lesion was present in the aorta. The heart, kidneys, liver, and lungs were normal.

Dr. Prudden also presented sets of cultivations which illustrated

THE BACILLI OF TYPHOID FEVER.

The *first* consisted of plate and tube cultivations from the fæces of a patient, thirty years of age, in the third week of the fever. The characteristic growth, however, can be best seen upon potato, where the bacilli form an almost invisible film.

The *second* were tube cultivations from the spleen of a typhoid-fever patient.

The *third* were tubes containing bacilli from specimens obtained in Koch's laboratory.

From a diagnostic point of view cultivations of this kind had considerable value; they were often successful, though not always, and it was not difficult to accomplish.

PAROVARIAN FIBRO-SARCOMA.

DR. E. M. CUSHIER presented a specimen with the following history: The tumor was removed four weeks ago, and presented some interesting and unusual features. The patient was thirty-seven years of age, had been married nine years, but had never been pregnant. Her general health was excellent until September, 1885, when she lifted a heavy weight. This effort strained her and gave rise to considerable pain, which passed away within two weeks, and she noticed then, for the first time, that there was a tumor in her abdomen. It grew quite rapidly, and in the following January she was so much distended that she could not get about. During January and February she was very feeble and extremely uncomfortable, but in March her size began to diminish, and this continued in April, and to such an extent that for three or four months she was so comfortable that she thought she was entirely rid of her abdominal tumor. When, however, Dr. Cushier saw the patient in November, the abdomen was very much distended, and presented the appearances of encysted dropsy. Nothing was felt except this fluctuating tumor. The diagnosis was possible ovarian cyst, probable parovarian cyst, because of the sudden disappearance at one time of the tumor.

The operation was performed on November 2, 1886. As soon as the peritoneum was divided, one of the cysts ruptured, and another ruptured almost as soon as it was touched, and the fluid presented the appearance commonly seen in the fluid of parovarian cysts. There was a pedicular attachment to the broad ligament. All the adhesions could be easily separated, except one, that necessitated the removal of a portion of the omentum. A portion of the ovary was left in the stump of the pedicle. The pedicle was so long that it allowed the tumor to go high

up in the abdomen, and it was found to contain a number of tubes, four of which had been opened, and all terminated by a blind extremity within the growth; they admitted an ordinary probe. They were regarded as enormously hypertrophied Wolffian ducts, which would make the tumor parovarian. Histologically it was a fibro-sarcoma, spindle-celled.

The pedicle was ligated with silk and dropped. The patient made a good recovery.

Dr. Putnam-Jacobi said that she examined the tumor with Dr. Cushier, and reached the conclusion that had been expressed concerning the tubes in the pedicle representing the remains of Rosenmüller's body, although she had not read of a case in which such hypertrophy had existed. She also referred to cases, reported by Dr. Goodell, in which abdominal cysts had ruptured and the patients recovered temporarily, and then they reappeared.

Dr. Ira. J. Van Gieson presented several excellent

STAINED SECTIONS OF THE SPINAL CORD

(stained according to Weigert's method) which showed some of the less frequent lesions, as solitary tubercle, acute polio-myelitis, etc.

Dr. Robert Newman presented a

TUMOR REMOVED FROM THE ROOF OF THE MOUTH

of a woman fifty-one years old. It had grown gradually during the last twenty years; more rapidly during the last five months. It was so hard that he was unable to remove it with Jarvis' snare, and used an écraseur. By the aid of cocaine the operation was painless, and there were no unpleasant after-effects. Only last week he had a case in which injection of twenty-five minims of a four per cent. solution of cocaine into the bladder was suddenly followed by an intense pain in the left temple, extending around the top of the head, with a feeling as if the whole top of the head had been blown off; the pain had lasted for ten days, with exacerbations.

The wound healed kindly in the present case, and was covered with mucous membrane. The specimen was referred to the Committee on Microscopy.

The Society then went into executive session.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, December 13, 1886.

Stephen Smith, M.D., Chairman; A. B. Judson, M.D., Secretary.

REMOVAL OF THE APPENDIX VERMIFORMIS BY ABDOMINAL SECTION.

Dr. J. D. Bryant reported a case of abdominal section for perforation of the appendix vermiformis. The patient was a man forty-five years old. Death occurred from exhaustion twelve hours after the operation. The patient was seen by Dr. Bryant about sixty hours after the first symptom, which was a slight diarrhœa. This was followed by pain, constipation, tympanites, nausea, and occasional vomiting. The pain was always in the epigastric region, and had been relieved at first by a cathartic. The vomited matter had not been characteristic.

The abdominal walls were found fully distended, without localized tenderness. The hepatic dulness was normal. There were no intestinal sounds or appreciable vermicular movements. Palpation and rectal exploration failed to assist in making a diagnosis. The temperature was 102° F., the pulse 108. It was clear that there was more or less general peritonitis, the result of either obstruction or perforation. The operation was performed with such antiseptic precautions as the circumstances allowed. No obstruction was found. The intestines and the caput coli were extremely distended. These parts, together with the sigmoid flexure, which extended across to the right iliac fossa, where the signs of inflammation were more intense than elsewhere, were deeply congested. Three perforations were found at the base of the appendix vermiformis, which was two and one half inches long, covered entirely with peritoneum, darkly congested, standing nearly erect between the intestinal folds, and presenting somewhat the outline of a small distended leech. It was tied at its base, below the perforations, and removed with the scissors. The abdominal wound was closed and dressed antiseptically, and a drainage-tube was inserted.

Dr. Jacobi referred to the redundancy of the sigmoid flexure in this case. It was a projection into adult life of a condition invariably found in the new-born. The moderate degree of the pain, its location, and its temporary cessation, rendered it not surprising that the diagnosis had not been made by the attending physician for a day or two.

Dr. Stephen Smith said that in his experience with such cases the pain had been, as a rule, relieved temporarily by a cathartic.

Dr. Bryant said that he had found great difficulty in keeping the intestines in place during the operation; a difficulty which, in another case, he would be prepared to lessen by releasing the gas with a trocar, closing the small intestinal wound with a suture.

CHRONIC HYDROCEPHALUS TREATED WITH INJECTIONS OF MORTON'S FLUID.

Dr. Robert T. Morris reported a case of hydrocephalus which was benefited by repeated aspiration and injection of iodine. The disease was of four months' duration. in a girl aged ten months, when he drew two and a half ounces of fluid from the left side of the anterior fontanelle, repeating the operation twice at weekly intervals, and then injecting half a drachm of Morton's fluid. Treatment was thus continued, with slight variations, for seven weeks, with manifest improvement, shown in the deportment of the child and in the arrest of the arachnoid dropsy. When twenty-two months old, however, the child suddenly died with rapidly recurring convulsions.

GALL-STONES ENCYSTED IN THE ABDOMINAL CAVITY—LAPAROTOMY—RECOVERY.

Dr. Morris also reported a case in which he had removed a tumor, supposed before the operation to be of pelvic origin, but which proved to be a fibrinous mass attached to the abdominal wall, and containing a collection of gall-stones, the sequel of attacks of hepatic colic thirteen years before. For several years there had been no indications of hepatic derangement. The patient was a woman, fifty-two years of age, who for a year had suffered repeated attacks of circumscribed peritonitis.

On examination the left ovary and tube, and the uterus, were found to be normal, but the right ovary and tube could not be found. There was a tumor in the middle line of the abdominal wall, with a fistula of three weeks' duration, discharging pus and a clear viscid fluid, about three inches below the navel. A probe would not follow the fistula. The tumor was immovable in the anterior abdominal wall, irregular in outline, painless on pressure, and not causing pain except during an attack of peritonitis.

The abdomen was opened in the middle line, and the right ovary and tube were found enveloped in a fibrinous deposit and drawn upward, but apparently in no way connected with the tumor. Exploration through the enlarged incision showed that the tumor had no close connection except with the abdominal wall and the intestines, which latter were firmly attached as a result of peritonitis. An incision showed the tumor to be a peculiar fibrous mass, honey-combed with little pockets containing brownish pus. It was decided to ablate the tumor; and a portion of the abdominal wall, three by two and

one-half inches, including the mass, was removed, an hour being occupied in dissecting away matted intestines and separating matted loops from each other. The last cut, at the upper end of the mass, opened a cavity in which were found six gall-stones; two of them each an inch in diameter, a third the size of a chestnut, and three not larger than kernels of corn. There was neither pus nor bile in this cavity. The little finger, following the line of a small closed canal along the site of the obliterated gall bladder and cystic duct, entered the common duct. On its withdrawal a flow of bile soiled the peritoneum in the vicinity. The margins of the canal were dissected up and sutured to the skin.

The wound, extending from the sternum to the pubes, was closed with difficulty. The skin and subcutaneous fat could be united, but the muscular margins remained three inches apart at one point. The most elaborate antiseptic rules were observed at every stage of the operation and dressing. There was very little shock. Primary union took place. The patient sat up in bed eleven days after the operation, and seventeen days later walked a quarter of a mile to the office of her physician. There is now, six months after the operation, apparently no danger from hernia and the patient is well, although a small opening still allows a scanty passage of bile to the skin.

The Section then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE CONTROVERSY ON LAPAROTOMY—SANITARY REGISTRATION OF DWELLINGS—THE LATE DR. NORMAN CHEVERS—A TIMID PATIENT—A NEW JOURNAL.

LONDON, December 14, 1886.

THE fierceness of the controversy which has been aroused in connection with the Liverpool Hospital for Women will probably be considerably quenched, now that the report of the Committee of Investigation has been published. Great interest has centred round the subject in London as well as in Liverpool. Candid readers of the report must confess, not only that the hospital is decidedly, though not severely, condemned, but that on the evidence brought before them the committee could have come to no other conclusion. They say that, in their opinion, "Sufficient care and discrimination have not been exercised in the selection of cases for operation, and that in many instances the gravity of the symptoms was not such as to have justified an abdominal section of any kind." They point out that the mortality after operations at the hospital for the removal of the uterine appendages has been between eight and nine per cent., and that, if the operation is performed for comparatively trivial affections, such a mortality constitutes a serious objection to the operation. That it has been, in their opinion, so performed is evidenced by the fact that they point out that one of the staff (Dr. Imlach) performed it eighty-five times during the year, whereas his two colleagues only performed it twenty-one times between them. They record their conviction that in some cases loss of sexual feelings and also loss of physical energy have followed the operation. In twelve per cent. of the cases hernia has followed. As a means of treating pelvic hæmatocele, the operation is unreservedly condemned. The committee conclude by recommending: (1) More frequent consultations among members of the staff; (2) that more information be given to patients before operating on them; (3) that patients be retained for a longer period in the hospital after operation, in view of the large number of cases of hernia occurring, and also because many patients discharged as cured had been obliged to remain in bed at their own homes for considerable periods; and (4) that in future only diseases of the female genito-urinary organs should be treated in the hospital, such operations as those for rupture, cancer of the breast, removal of the spleen, and opening the bowels for rectal cancer, being relegated to a general hospital.

At a recent meeting of the Society of Medical Officers of Health a discussion took place on the question of the sanitary registration of dwellings. Mr. Mark Judge, a well-known architect, read a paper on the subject in which he very carefully and fully treated it. Mr. Judge is of opinion that every house should be carefully inspected, and that if its sanitary arrangements are defective they should be rectified. A bill on the subject is shortly to be presented to Parliament, though whether it will pass is more than doubtful. Anything to curtail the liberty of the subject is extremely obnoxious to the average Englishman, as witness the opposition to *compulsory* vaccination, even among educated persons who know its value. Even Mr. Ernest Hart, when a candidate to represent an East End constituency in Parliament, intimated that he would vote for the abolition of *compulsory* vaccination. The views advocated by Mr. Judge are therefore not likely to become law without a struggle.

The death of Dr. Norman Chevers is announced. Dr. Chevers was a distinguished Indian medical officer, and was for many years Professor of Medicine at the Calcutta Medical College. He retired from the Indian medical service in 1876, and for a few years filled the post of warden to the London Hospital Medical College. His contributions to literature have been numerous. Of these, perhaps the most noteworthy and important was his "Manual of Medical Jurisprudence for India," for which he received a valuable prize a few years ago.

Probably some of your readers are familiar with the story of the ancient spinster who, on asking a rising laryngologist how far he could see, was considerably discomposed by his prompt reply, "Far enough, madam, to see that you are sitting on a cane-bottomed chair." A companion story to the above was told to me a few days since, and, as it has the advantage of being true, I will give it for the amusement of your readers. In the out-patient department of one of the largest metropolitan hospitals a boy was recently being ophthalmoscopically examined. One of the by-standers observed him to be trembling from head to foot, and, when it came to his turn to have a look at the fundus, asked the boy kindly what ailed him. "Oh, sir," said the boy, "I'm afraid to think anything." "Well," said his examiner, "I don't see much brains. I don't think you could think much if you tried to," a rejoinder which apparently consoled the boy not a little.

The mention of laryngology reminds me that a new venture in journalism is just announced. It is to be entitled *The Journal of Laryngology and Rhinology*. Dr. Morell Mackenzie is to be the editor, and he is to be assisted by thirteen *collaborateurs*, among whom, however, I notice the names of only two Englishmen, both young men who are just beginning the study of the subject, and who joined the staff of the Throat Hospital after the disruption of its experienced staff last spring.

OUR PARIS LETTER.

(From our Special Correspondent.)

INTELLECTUAL DIFFERENCES IN SAME ETHICAL GROUP—THE HEALTH OF PARIS FOR 1885—THE EXISTENCE OF MAN IN EUROPE AT THE TERTIARY PERIOD—ANTIFEBRINE—SELF-IMPOSED STARVATION.

PARIS, December 10, 1886.

IN a paper on the intellectual differences in the same ethnical group, read by Dr. Fauvelle at the last meeting of the Association Française for the Advancement of Science, the author reminded the audience that the in-

telligence is the manifestation of nervous influx into the gray cortical layers of the brain, manifestation especially characterized by memory and the will. He gave a succinct description of the structure of the cerebral centre. He then divided the intellectual differences into *subjective*—that is to say, depending on the organization itself—and *objective*, resulting from the influence of media, and particularly from education and instruction. After having enumerated these differences, Dr. Fauvelle sought to explain how, in the midst of so many variations, the human cerebral type not only maintains itself, but progresses in a continued manner. He finds the explanation in that in every society the rôle of individuals changes at each generation, and that thus all the variations, all progress, of the cerebral organ are propagated and generalized by heredity. He then concludes that, as democracy prevents the formation of castes, and consequently the maintenance of the same functions in the same families, it is the social form the most hygienic for the intellectual centre. The idea is rather far-fetched, and must be accepted with some reserve.

M. Bertillon, Director of the Statistical Department at the Prefecture of the Seine, lately published a statistical report on the health of Paris for 1885, in which the author draws a comparison between the capital and some of the chief provincial towns. According to the report, Marseilles is the most unhealthy. For instance, typhoid fever is fatal in London and Berlin to 17 inhabitants in 100,000, 14 at Vienna, 19 at Brussels, 63 at Paris; whereas at Marseilles it carries off 149 per 100,000. Small-pox is also more prevalent at Marseilles than at any other city, the deaths having numbered 91 for 100,000 inhabitants. At Paris there were only 12 deaths, and at Berlin 5, for the same proportion. In the Prussian capital vaccination is compulsory; but while it is favored in this respect, it is less so for other affections. For instance, there were 140 deaths from croup for 100.000 inhabitants, while Paris counted only 80, and Marseilles 98. In London the figure for 1885 was 22 deaths from croup for 100,000 inhabitants. Scarlet fever appears to spare Paris more than any other capital. In this city there were 7 victims to the disease for 100,000 inhabitants, but in London there were 17, 31 at Berlin, 10 at Vienna, 28 at Brussels. Among the French cities Marseilles heads the list for insalubrity, for scarlet fever there were 23 deaths for 100,000 inhabitants. M. Bertillon also gave a report of the funerals that took place in 1885. At Paris, for 100 funerals, 28 were purely civil—that is, without any religious ceremony—and the proportion was greater among the poorer classes than among the rich and well-to-do. As regards criminality, or moral hygiene, as it is termed, there were 41,152 individuals arrested in Paris, of whom 35.078 were men and 6,074 women. Among the men were counted 2,469 foreigners. About a third of the arrests among the men (13,549) were for vagabondage or for mendicity. Of the number of males arrested for vagabondage or other causes, 3,218 were under twenty-five years of age.

At a recent meeting of the Academy of Sciences, M. de Quatrefages, the celebrated ethnologist, read a paper in which he endeavored to prove the incontestable existence of man in Europe at the tertiary period. He observed that the extension of man of the quaternary period in all the regions, and up to Patagonia, suffices to render evident his existence anteriorly. The author adds that if tertiary man (the cannstadt race) is indiscutable in Europe, nothing till now indicates his existence in America. He concludes with the belief that the primary cradle of humanity was the extreme north of Asia.

Antifebrine, the chemical name of which is acetanilide, has recently been introduced into therapeutics as a febrifuge. It is a crystallized substance, whitish, little soluble in water, but easily so in alcohol. It has scarcely any appreciable taste. Dr. Dujardin-Beaumetz, who reported on this new medicament at a recent meeting of the Société de Thérapeutique of Paris, represented it as an antithermic in doses of from twenty-five to fifty centigrammes; it lowers the temperature and provokes abundant perspiration. In larger doses, like carbolic acid, it determines cyanosis. In phthisical subjects it has not produced any favorable results. The members present almost unanimously condemned antifebrine as a dangerous antipyretic, and preferred having recourse to antipyrine, which, at least, does not offer any danger, provided it is not administered in excessive doses.

I have just seen Merlatti, one of the Italians in Paris who are passing through the ordeal of self-imposed starvation. From what I had read in the public press, I had expected to find a man in bed in a semi-cadaverous condition; but to my surprise, I saw a young man a little over twenty, moving about with as much agility as would have a man of his age under ordinary circumstances. He was being photographed in various postures, which is in itself a very fatiguing undertaking. During my visit I cannot say that I was favorably impressed with the genuineness of the experiment; for although the man was certainly emaciated, he was not so to the extent that one would have expected on this his forty-fifth day of fasting, as he is supposed to live on nothing but cold water. His weight, according to the report of the doctor in attendance, is forty-four kilogrammes five hundred grammes, his original weight having been six kilogrammes two hundred grammes. He is not being watched so closely as he used to be, as since the thirtieth day of his fasting, when he was advised to discontinue the ordeal, owing to alarming symptoms having set in, he is, according to his express wish and on his own responsibility, allowed to complete the fifty days agreed upon. As for Succi, the other Italian, who has reached the tenth day of fasting, he is doing well, and even appears to be fattening on his starvation—which he attributes to the peculiar virtues of the liquor that he pretends to have discovered, and which he takes. This liquor is said to have the property, not only of assuaging the pangs of hunger, but of preventing the too rapid waste of the tissues of the economy.

Owing to the retirement of Professors Gavarret, Hardy, and Sappey, Professor Potain succeeds to the chair of clinical medicine at the Charity Hospital; Professor Peter takes M. Potain's place at the Necker Hospital. The chair of anatomy and that of medical pathology are vacant. The former is likely to be filled by Dr. Farabeuf, and the latter by Dr. Dieulafoy. The chair of medical physics is virtually filled up by Dr. Gariel, who has been acting for Professor Gavarret for some time.

An international exhibition of hygienic apparatus is to be opened at Lyons on the 15th inst., and will be continued to February 7, 1887.

NOTES OF A VISIT TO PASTEUR'S LABORATORY.

To the Editor of The Medical Record.

Sir: This morning I had the pleasure of visiting the institute where at present Professor Pasteur practises the inoculations for the prevention of hydrophobia in persons bitten by animals suffering with rabies. The modest building containing the various rooms is a low, one-storied structure, temporary in character, and is situated in the court-yard of one of the schools and laboratories for physical research, No. 14 Rue Vaquelin (the school or Latin quarter), an elevated portion of the city on the south side of the Seine, not far from the Panthéon. The rooms include registering, waiting, operating, a small surgery, and a private apartment for M. Pasteur. Visitors are requested (by a printed notice) to procure introductions and cards of admission through their respective ministers or consular officers—if foreigners—but admittance is not denied to medical men sending their cards, and the stranger will meet M. Pasteur and his assistants

and be shown every courtesy and attention. Upon this morning I saw the patients come into the inoculating-room in batches of about fifteen. Led or moved up to the principal assistant, they were singly and quickly treated to the hypodermatic injection of the all-important protective fluid with a simple plunge of the charged instrument, usually into the lumbar region or loins. There was no delay, the patients being prepared and with the clothing removed at the part indicated. They were operated upon in rapid succession, the syringe being charged freshly each time by the assistant whose duty it is to prepare and conserve the inoculating material. The syringe is apparently the ordinary glass and white-metal instrument, and it is introduced in an oblique direction nearly up to the cylinder, and then rather quickly discharged. The patients come and go, for the most part, quite unconcerned. The new patients, naturally, are in some trepidation, while the children commonly set up a howl and struggle somewhat. The parents usually accompany children—the mother often holding her child—friends or relatives are with the adults, and in many cases the local physicians are in attendance. M. Pasteur stands near by, seeing all things done, and constantly speaks cheering words, or soothingly pats a child. Great attention is given to the eliciting of accurate information and details regarding each case, and official documents from physicians, veterinary surgeons, and from those in authority whence patients come, are always required. All possible sources of error are carefully inquired into, and the truth in each case is sought for in a most systematic and painstaking manner.

Besides the people necessary for registering and attending to minor details about the establishment, M. Pasteur had on this occasion four assistants: two attending to the giving of the injections, the same one always using the instrument; one fluid conserver, who charged the instrument (plunging the needle into the cup containing it through a cover of filtering-paper); and one who examined patients—their wounds, condition of health, etc.

On this morning there were treated eighty patients, ten being present for the first time. They were from all countries and of all conditions of life: the gentleman, the laborer, soldiers, sailors, peasants, some colored people, and men, women, and children. There were a few instances of two and three members of the same family. The inoculations, so far as I could learn, produce no points of irritation, and they are almost without exception made into the region of the loins.

It is a most impressive and wonderful scene, for one cannot but reflect upon the doubts and opposing views still coming from many able men, and upon the possibilities of disaster yet before many of these unfortunate people, in view of the frequent long period of latency of the disease; and there rises up in the mind some of the results predicted by M. Pasteur's opponents, that these inoculations *produce* rabies in subjects otherwise free of the terrible virus. The spectacle is in these respects extraordinary, for there undoubtedly still exists a doubt as to the utility of these inoculations, and in some minds a belief that people are perishing from them. Exaggerated reports regarding the fate of some of the patients are frequently met with in some of the French medical journals, but they are nearly always unfounded.

Up to August 1, 1886, the number of patients (Frenchmen) subjected to prophylactic treatment was 1,500, of whom only 10 died. At least eighty per cent. of these cases received bites from undoubtedly rabid animals; so that 973 individuals were bitten. It is computed that 155 of this number would have died if they had been left to themselves, and yet there had been but ten deaths. Dr. Chautemps hence claims that M. Pasteur had saved the lives of 145 of his countrymen.[1]

From what has gone before, and from M. Pasteur's labors and statistics, assuming that the margin of error in his great work is small, and this it seems must be admitted, there is hardly room for doubt that a great number of people are being saved from a horrible death, and that the mortality of those bitten—authenticated cases—has been most remarkably diminished. Therefore, for the present, the evidence is accumulating in favor of M. Pasteur, and we must believe in the practical life-saving value of his discovery.

In the court of the École Normale, in the Rue d'Ulm, No. 46, there is a series of ground-floor buildings, the rooms of which are given up to another part of the work—experimental physiological work, inoculation of rabbits, glass-working in tubes, bulbs, etc.; there are also cases containing monkeys, rabbits, and chemical apparatus. I here witnessed dissections of the spinal cord and the trepanning of rabbits in connection with the inoculations. The operator in trepanning the skull first places the animal prone on a stout piece of board—somewhat longer and wider than itself—ties its legs with cords passing through holes near the edges, and places a cover of filtering paper saturated with chloroform over the nose and head. In a few moments the animal is anæsthetized; he then clips off the hair from the vertex with curved scissors, makes an incision one and one-half inch long, and readily exposes the bone directly at the crucial ridge. He then inserts a pair of spring retractors to keep the wound well open, and while an assistant steadies the head by the hands on the animal's nose and occiput, he applies the trephine, and with a few turns the guard flange of the instrument has come down on the surface of the external table, and the little circlet of bone (three-sixteenths of an inch in diameter) is readily removed with a small hook. The virus to be injected is then sent under the edge of, and away from, the opening into the brain, superficially, and just under the meninges, with a well-curved fine hypodermic needle. If there is any detritus or blood, it is mopped up with a little filtering paper moistened with an aseptic lotion. Two stitches bring the wound together, it is again mopped with the aseptic lotion, and the operation is completed—the animal regaining consciousness as it is being replaced in the basket. There is no brutality, the animal is not conscious of any pain, and the operation is completed in from three to five minutes. The rabbit furnishing the material had been dissected and the cord exposed but a short time before, and the work had been most beautifully done.

SOME RECENT OPPONENTS OF M. PASTEUR.

Within a few months M. von Frische, of Vienna, working under the auspices of a society of ladies of that city, has published his investigations on the value of the anti-rabic inoculations of M. Pasteur, and, as far as they go, they seem to be more or less contradictory to those of Pasteur. Upon this M. Drasche, Professor of the Faculty at Vienna, discusses unfavorably the work of Von Frische, in that it compares poorly with M. Pasteur's work in method, delicacy, and materials; that the number treated (eleven) was small on which to base such conclusions; and that the virus used was not sufficiently attenuated, in all probability. In other words, Professor Drasche refuses to believe that the work of Frische has any value concerning the question of the preventive treatment of hydrophobia by anti-rabic inoculation, and that he has not exactly followed the procedures of M. Pasteur.

The results published concerning the mortality among the patients of the Pasteur Institute at Odessa are reported as being "most deplorable."

In the *Revue Scientifique* for August 21, 1886, there is mentioned a Polish physician, le Docteur Prince Ignace Jagell, who since 1858 has been searching for means to combat hydrophobia. He refuses to admit that sufficient preventive virtue can follow from virus obtained from so inoffensive an animal as the rabbit (after M. Pasteur's method). He thinks that bites from rabid animals through the clothing are always incapable of transmit-

[1] Lecture at Sorbonne, October 10, 1886.

ting the virus, and he maintains that the deaths among M. Pasteur's patients are always from among those bitten in parts unprotected—true cases of hydrophobia from the bites of rabid animals. He also declares that he has treated eighty-eight cases of bites from rabid wolves and dogs, and all have been cured by the infusion of the bark of *Spirea filipenda;* twenty-six of these cases having been found in the first stage of hydrophobia when treatment was commenced.

The same remedy is also mentioned in recent numbers of German medical journals.

REMARKS IN CONCLUSION.

There are at present competent commissions laboriously attending all the steps in the Paris laboratory with a view to prove or disprove, as far as possible, the value or utility of anti-rabic inoculations for the prevention of hydrophobia. There is required only a proper interval of time for this, as the solution of all momentous questions have necessitated. In the meantime the works and speculations of single investigators elsewhere can amount to but very little. The final seal of approval or disapproval will be given at Paris and Berlin, for in no other countries does the state aid as much, nor are the laboratories so complete. In both France and Germany the government in all ways directly fosters and aids in the solution of such great public questions. Opposition and unfavorable criticism exist in all countries, much of it in exaggerated phraseology; and if one read or saw nothing else—much less, had no personal observation of affairs at the Paris laboratory—it is conceivable that from opposition it would be but a step to calling for violent interference with M. Pasteur. There is, however, incontestable truth in the science of preventive medicine, and more or less in M. Pasteur's theory of combating disease in man and animals, much as it may be obscured by the clouds and mists induced by the present defective methods of investigation. Long before Jenner, the Orientals and Chinese practised inoculations for the prevention and amelioration of disease, and now, in this nineteenth century, why not M. Pasteur with the attenuated anti-rabic germ, and a Koch with an equally disarmed bacillus?

In this direction medical science is now steadily advancing, clearing away the *doctrinaires* and mounting upon the higher plane of ascertained facts and truths of modern experimental research, yet continually being tested in the fires of adverse criticism. It is now the brain working more with the eye and hand, where formerly hair-splitting theorizing in the sea of clinical observations absorbed all the faculties of the leading men.

It is not disputed that putrefaction, fermentation, and the causes of other low forms of life are now well known, and that these but precede the more important and deeper studies known under the general term bacteriology. It is not necessary to mention here the list of disorders and diseases, local and general, occurring in the animal kingdom and in man, influenced and caused by bacteria wherein opposing argument has in great part ceased.

Aseptic surgery cannot be denied its superiority, whether it consists in absolute purity of surroundings and other natural means of attenuation and dispersion of germs, or in the paraphernalia of its strictest exponent; and it has not been my fortune to see elsewhere such general success with operations as I had the pleasure of witnessing recently in Paris, at the Hospital Tenon, under Dr. Championnière, and in Edinburgh under Dr. Cheyne. Recent surgery is eliminating the former well-known mortality from joint-operations, laparotomy in its general sense, and trepanning the skull, whilst diagnostic incisions are now recognized legitimate procedures.

The history of life and of disease in all nature is being accurately revealed in all its possible bearings, and the lessons of that knowledge are being utilized for the conservation of human existence. Applying to organic beings in apparent health attenuated virus, or disease-germs modified by culture, by inoculation or by any means whatsoever, to procure a protective influence, is a result arrived at by the present studies of M. Pasteur and men like him. Similar conclusions follow observations upon the well-known protective effects of acclimation, workmen in sewers inspiring polluted air constantly, etc.

In conclusion, it will not be out of place to mention here a very recent and most remarkable advance made in the power of the microscope, effected in Germany, with the support of the government. It consists in an improved lens, composed of a newly discovered quality of glass of great hardness, permanency, and freedom from color, and cut according to a new system of curvatures. At a late meeting of the Royal Society it was asserted that the general power of microscopes would be increased thirty per cent., consisting chiefly in greater achromatism of the objective.

CHARLES A. SIEGFRIED,
Surgeon, United States Navy.

SOME POINTS CONCERNING INTUBATION OF THE LARYNX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Will you kindly allow me a communication, in order that, through your columns, I may answer the many questions which come to me through the mail regarding intubation of the larynx.

My paper before the Academy of Medicine was written for the audience, and not for print. I see, since its publication, how incomplete it was when it came to be read outside of New York.

I will try and answer the questions that have been written me, and anticipate one or two.

First, the tubes known as O'Dwyer's tubes for intubation of the larynx for the relief of laryngeal stenosis are, with latest modifications, made by and for sale by George Tiemann & Co., New York City. These tubes, five in number, are of different sizes, appropriate for children from infancy to twelve years of age. The remaining instruments of the set are inserting-instrument or handle, extractor, mouth-gag, and gauge. The price for the complete set is $35.

As to indications for operation. First, be sure of the diagnosis. Is the dyspnœa due to laryngeal stenosis? I have been called several times to insert the tube where the dyspnœa was marked, and yet not of laryngeal origin, and a tube would afford no relief.

To determine this point the chest must be examined. If the thorax expands and contracts freely, and air enters all parts of the lungs freely, the dyspnœa is not due to laryngeal obstruction. Recessions and diminished vesicular murmur over the lower posterior portions of the lungs argues that it is of laryngeal origin.

When shall the tube be inserted? When the laryngeal obstruction has advanced to such a degree that air no longer enters freely all parts of the lungs. Wait for cyanosis? By no means. Neither wait for this "danger-signal," nor till the patient is exhausted from labored respiration and restlessness and sleeplessness, nor till the lungs are injured from collapse and congestion. Ordinarily the course is as follows: Croupy cough, then croupy respiration, restlessness, and recessions, cyanosis. As soon as the entering air ceases to give low-pitched vesicular murmur, which in a child with accelerated respiration should be very distinct, it is time to insert the tube.

It is my experience that a narrowed larynx causes an increase in the frequency of respirations, and on inserting the tube and relieving this condition the respirations, at once become slower. They may fall from thirty-six to twenty-two immediately.

Each instrument-case should contain braided silk of such size as to run freely through the eyelet of the tube.

If the silk is twisted instead of braided it may fray out and become jammed in the eyelet. This should be cut eighteen or twenty-four inches long, passed through the eye to the middle of its length, and the two ends brought together. Some tie the two free ends together, but that is not necessary. When the obturator is pushed into the tube the thread should be made to lie in the groove of the obturator. When properly placed the thread is of service in wedging the tube upon the obturator, maintaining it in position.

When should the thread be removed? I remove it as soon as the child inspires once and shows the tube to be in position, and before removing the gag. It can do no harm to wait longer, but the thread may become entangled and drag out the tube. Waiting necessitates putting in the gag again, and this time the child will object. In withdrawing the thread pass the left index-finger into the larynx upon the head of the tube, and hold it from coming out, while with the other hand grasp one of the free ends of thread and so pull it away. Having removed the thread, as a last assurance press the head of the tube well down into the box of the larynx, and when all is done remove the gag. The shorter the time the jaws are pressed widely apart the less the exhaustion. From the time the child is in position and the gag well placed, the remaining manipulations need require no more than fifteen to twenty seconds.

Some of my correspondents have used chloroform, both in inserting and extracting. With the tendency to heart failure in diphtheria, I could not but feel this to be very hazardous and would by no means recommend it.

The position of the child as recommended in the paper cannot be too strongly urged. The tube and the handle when ready for insertion are at right angles to each other. So, too, the axis of the trachea and of the mouth should be at right angles. The child should be placed "as though it hung from the top of its head." The nurse should sit in a straight-backed, steady chair, hold herself straight upright, and grasp the child by the elbows, while she restrains the child's feet between her knees. In addition to this, an assistant should stand behind the nurse, place a hand on each side of the child's head and face, and hold it firmly. He cannot in the same grasp include the gag and hold it secure.

The modified mouth-gag of Dr. Denhard seems to me to be an improvement on that of Dr. O'Dwyer. The child by raising his shoulder may displace the latter, and to meet that difficulty Dr. Denhard has carried the levers straight back toward the ear instead of allowing the downward direction of the original gag.

The modified gag is made by Tiemann & Co., and must be specially mentioned, if desired, when ordering sets of instruments.

What medicine is to be given after the tube is in? Answer: Milk and whiskey. I have occasionally found my tubes well corroded when enthusiasts in bichloride treatment and advocates of iron have been hard to manage. Any rectal medication is without objection, and quinine suppositories are much used by Dr. O'Dwyer.

One correspondent states that he received a set of tubes, and before he could practise on a cadaver had a call to a croup case, and succeeded without difficulty in inserting the tube.

Yours truly,

W. P. NORTHRUP, M.D.

57 EAST SEVENTY-NINTH STREET, NEW YORK,
December 25, 1886.

URETHAN FOR THE INSANE.—Dr. Sighicelli has found urethan of service in certain forms of insanity, especially in mania. He ascertained also that while in most forms of mental trouble no additional effect was caused by an enlarged dose, in mania the intensity and duration of the sleep increased with the increase of dose. In dementia, idiotcy, hysteria, and epilepsy, the drug was of less service.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 19 to December 24, 1886.

FORWOOD, W. H., Major and Surgeon. Granted leave of absence for one month. S. O. 129, Department of Dakota, December 16, 1886.

LAUDERDALE, J. V., Captain and Assistant Surgeon. Ordered from Fort Concho to Fort Clark, Tex. S. O. 174, Department of Texas, December 16, 1886.

EVERTS, EDWARD, First Lieutenant and Assistant Surgeon. Ordered from Fort Grant to Fort Apache. S. O. 136, Department of Arizona, December 16, 1886.

MASON, CHARLES F., First Lieutenant and Assistant Surgeon. Ordered from Fort Huachuca to Fort McDowell. S. O. 136, Department of Arizona, December 16, 1886.

BANISTER, W. B., First Lieutenant and Assistant Surgeon. Ordered from Fort Wingate to Fort Lowell. S. O. 136, Department of Arizona, December 16, 1886.

DIETZ, W. D., First Lieutenant and Assistant Surgeon. Ordered from Fort Stanton to Fort Bayard. S. O. 136, Department of Arizona, December 16, 1886.

POLHEMUS, A. S., First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon at Fort Gaston, Cal., relieving. S. O. 123, Department of California, December 13, 1886.

RAYMOND, H. I., First Lieutenant and Assistant Surgeon. Ordered for duty at Angel Island, Cal. S. O. 123, Department of California, December 13, 1886.

ANDERSON, C. L. G., First Lieutenant and Assistant Surgeon. Assigned, temporarily, to duty at Whipple Barracks, Ariz. S. O. 132, Department of Arizona, December 7, 1886.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 25, 1886:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	3
Scarlet fever	34	7
Cerebro-spinal meningitis	5	2
Measles	497	58
Diphtheria	123	47
Small-pox	0	0
Yellow fever	0	0

VERY EARLY VOTING.—Our fiery friend Daniel, in his *Texas Medical Journal*, shifts the heavy political responsibility of the following quotation on the *Nashville Journal of Medicine*, "For voting of infants, one grain of calomel to one ounce of lime-water; to this add one pint of pure water, and give a teaspoonful of the mixture every ten minutes."

THE LAY PRESS AND QUESTIONS OF PUBLIC HEALTH.—The *Sanitary Engineer*, speaking of the relation of the daily papers to the accomplishment of sanitary improvements, points out that progress in the improvement of health, the diminution of sickness, and the lengthening of life depends in part on the increase of human knowledge of the laws of physics, chemistry, and

biology, and in part on the diffusion among the people of the practical deductions from this knowledge. Sanitary legislation and improvements for any given community must be regulated very largely by the opinion of the majority of the taxpayers and voters in that community as to the necessity for them, and hence, to obtain action for securing a purer water-supply or a better system of sewage disposal, it is not sufficient that a few skilled engineers and physicians are satisfied of the need of the improvement, and of its practicability at a reasonable expense, but the people, from whose hands the funds are to come, must also be "educated up" to the requirements of the situation. This is, of course, a legitimate and an important mission for the public press. That it is often most worthily discharged is thankfully admitted. But that this responsibility is also liable to abuse is well pointed out by our contemporary. "The chief defect of newspaper sanitary literature, taken as a whole," it says, "is its tendency to exaggeration and sensationalism, and its liability to be dictated or inspired by a desire for an advertisement. The man who is interested in a patent filter is ready to furnish a column or two on the impurities of the water-supply, with, it may be, a few choice engravings representing strange forms which he tells the shuddering public are entomostraca, desmids, etc. He is careful not to explain that these organisms live in pure water—in fact, that they cannot live in water that is very impure. The man with a patent trap wants to arouse the people to a sense of the dangers of sewer-gas; the dairyman wants to explain the poisonous properties of oleomargarine; the man who failed to get the appointment of health inspector wants to show up the negligence of the health department, and each and all of them do the best they can to get some newspaper to publish their philanthropic essays. To those who know how much of this sort of matter is floating round in manuscript form in our large cities the wonder is, not that our newspapers should publish so much rubbish in the way of sanitary letters, etc., but that they should publish so little as they do, and when alarming stories alleging a dangerous condition of the Croton water appear in our daily papers it is safe to assume that the editor has been deceived, or the business department have inserted the matter as 'a reading notice' at so much a line."—*The Boston Medical and Surgical Journal*, October 7, 1886.

"Bumm on a Diplococcus" is the title of one of the papers contained in the report of the Würzburg Medical Society for 1885. The author, Dr. Bumm, found the diplococcus in the pus of a mammary abscess.

To Inspire Confidence.—A dentist in Mexico had a patient who was timid about having a tooth extracted. To show him that the operation amounted to nothing, the dentist called the boy who wielded the mallet and, telling him to open his mouth a minute, pulled at one of his teeth. The patient was not reassured, and the dentist lost his small boy.

Ether Spray in the Pains of Locomotor Ataxia.—Dr. Raison states that he has succeeded in completely controlling the pains of locomotor ataxia by means of ether spray directed against the most sensitive point and carried a short distance upward along the course of the nerve-trunk supplying the part. The application should be carried to the point of congelation of the skin, and its good effects are increased by at the same time directing a current of air from a bellows upon the parts to which the ether spray is applied.—*Journal de Médecine et de Chirurgie Pratiques.*

The Cosmetic Effect of Small-pox.—Dr. A. S. Deane, writing in the "Chinese Customs Medical Reports," says that when he was physician to a large fever hospital in Ireland, a young girl was admitted in the vesicular stage of semi-confluent variola. He was experimenting at the time on the various methods proposed for preventing pitting. The plan adopted in this particular instance was to cover the face with a paste of whiting mixed with carbolized oil, while the patient's hands were confined in a sort of strait-jacket. The result was eminently satisfactory. No scar remained anywhere, except on the point of the chin, where the friction of the bed-clothes continually rubbed away the application. Previous to her illness the girl's appearance was homely in the extreme, but she was discharged in possession of a dimple on her chin which lent her a bewitching air whenever she laughed, and from that time out she carefully cultivated a cheerful expression of countenance.

The Poor of New York.—The registration bureau of the Charity Organization Society records a list of 71,332 different families, or a total population of 285,000 individuals, involved in mendicancy or dependence.

Chian Turpentine in Cancer.—Dr. John Clay reports three more cases of cancer cured by Chian turpentine. Dr. G. W. F. Bury reports also a very striking case with a similar result. On the other hand, Dr. William Dale says that the drug was tried in the cancer wards of the Middlesex and of the W. Norfolk and Lynn Hospitals without result.

The Treatment of Asthma by Large Doses of Tincture of Lobelia is recommended by Dr. Nunes (*Bull. Gen. de Ther.*), who attributes failures with that drug to its use in too small amounts. Dr. N. gives ʒ ss. to ʒ j., combined with benzoate of ammonia. The following cases are alluded to in Nunes' communication: A man, fifty-six years of age, was suffering for a year from strong dyspnœa and coughing, interfering with his sleep. On auscultation whistling and bellows-sounds were heard. Heart and blood-vessels were normal. Nunes prescribed: ℞. Tinct. lobeliæ, f ʒ iv.; ammon. benz., ʒ iiss.; aquæ dest., f ʒ vii. M. S.—A tablespoonful every two hours. Later the quantity of lobelia was doubled. The patient recovered completely. A man twenty-four years of age suffered for three years from dyspnœa and cough. The vascular system was normal, but the liver was enlarged. The latter condition was removed by giving the patient: ℞. Calomel, gr. viii.; pulv. rad. rhei., sacchar., āā gr. vii.; S.—Take before retiring. Later the following was prescribed: ℞. Tinct. lobeliæ, f ʒ v.; ammon. benz., ʒ iii.; aquæ dest., f ʒ vii. M. S.—Tablespoonful every two hours. After three days, cough and dyspnœa had decreased. Nunes then ordered: ℞. Terpine, gtt. 15; mixt. gumm., f ʒ vii. S.—Tablespoonful hourly. As the condition of the patient grew worse, Nunes resorted to the dose of 1 f ʒ of lobelia in 7 f ʒ of water, as given to the first patient, whereupon the patient recovered. In two other cases, Nunes obtained the same favorable results by equally large doses of the tincture of lobelia.

An Irish Health Resort.—Surgeon-General Gordon writes in the *Medical Press* calling attention to Lisdoonvarna, in County Clare, Ireland, as a health resort. He says it is delightfully situated on high land exposed directly to the winds from the Atlantic Ocean. The wells are sulphurous and chalybeate, and the waters enjoy a high reputation in the neighborhood in the treatment of eczema and psoriasis, chronic rheumatism and gout, scrofula, chlorosis, and certain forms of dyspepsia.

Microbes in Urinary Calculi.—At the Paris Biological Society, M. Galippe stated that he had examined arthrophytes removed from a knee, and had observed microbes in them the same as he had detected in calculi removed from the bladder; he had isolated them and cultivated them. This investigator is therefore confirmed in his belief that the crystallizations found in the human economy develop through the agency of microbes.—*New Orleans Medical and Surgical Journal.*

THE CURE OF POTT'S DISEASE WITH RECESSION OF THE DEFORMITY.[1]

BY HENRY LING TAYLOR, M.D.,

NEW YORK.

A PROFOUND change in the prognosis of vertebral caries has been witnessed within a generation. In spite of the intelligent labors of Pott and his successors, the malady which bears his name was regarded, thirty years ago, as one of the most unpromising, if not hopeless, with which the surgeon had to deal.

It was thought to be the expression of a constitutional taint so vicious that its victims could scarcely hope to escape contractions, abscesses, paralysis, visceral degenerations, or general marasmus. A fatal issue was not believed to be doubtful for very many, while the unfortunate survivors would be obliged to carry through life the hideous mark of their disease. This unfavorable view was justified in the main by the natural history of the affection, and these unfortunates can still be observed in various stages of disintegration wherever they do not have the benefit of modern methods of treatment. The few cases of spontaneous cure with moderate deformity, especially when the disease is located in the lumbar region, and the more numerous examples of restoration to fair health after long-continued disease, and in spite of great deformity, emphasize these statements rather than impeach them.

The mechanical conditions presented by the locally softened or disintegrated column furnish a plain indication which has been generally recognized and acted upon by orthopædists. Modern methods of providing local rest and protection without confinement meet this indication more or less perfectly, and have considerably modified the prognosis. The more adequate of these methods, efficiently used, have proved so successful that we now regularly expect, with faithful home care and co-operation, and barring accidents, to check and heal the caries in all but the last stages, and to restore the patient to health and usefulness. Even in long-standing and complicated cases, often satisfactory, and sometimes brilliant results can be obtained. There are, indeed, very few cases where correct mechanical methods and painstaking attention will not effect a complete cure, and such exceptions will be found only, I believe, in the last stages of the disease or in constitutions vastly more depraved than those of our average subjects.

Admitting that the main object of treatment, the cure of the disease, can, with favoring conditions, usually be attained, how does the case stand with regard to the deformity, a question scarcely second in importance in the mind of the patient and his friends.

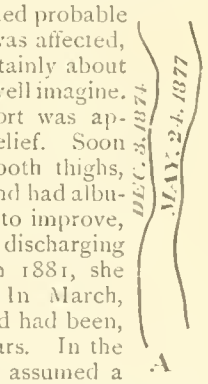
It is fortunate that the protective means employed to arrest the morbid process tends not only to prevent increase of deformity by checking the disintegration in the acute stages of the disease, and the yielding and compression of the new tissues which inevitably occur where protection is too soon discontinued, but that it can also be so used as to cause positive amelioration of the deformity in many cases, and absolute recession in a few. It can be made to develop whatever capacity of straightening there is in the compromised column.

The average ultimate result in Dr. C. Fayette Taylor's private practice, using his antero-posterior leverage supporting and protecting apparatus thoroughly and for a sufficient length of time, has been, under favoring conditions of attendance and home attention, the definitive arrest of the deformity at or near the point it had reached before such protection was furnished. A moderate amount of immediate straightening is not uncommon at the beginning of treatment, and this gain can frequently be maintained where home attention to the details of treatment is satisfactory. Compensatory curves above and below the seat of disease can often be modified by adaptations and adjustments of the pressure and leverage of the apparatus, and the figure may sometimes be notably improved in this way, even in apparently desperate cases.

There remains, however, a small class of cases where the deformity increases in spite of good care, and a larger class where, owing to too infrequent visits, which preclude those progressive and delicate modifications of detail which the varying indications of the disease demand, and which are so essential to proper support and to the best results, or to the lack of patient, intelligent, and painstaking home attention, there will be gradual, and, it may be, extensive increase of deformity.

It should be said, however, that owing to differences in constitution, or in the grade of the morbid process, many cases will do well under more or less unfavorable conditions. Such results may be thankfully accepted, but they cannot be counted on. It is also true that in cases of extraordinary severity in depraved constitutions the deformity can sometimes be arrested by exceptional attention and care, even where a fatal result cannot ultimately be averted.

This is shown in the case of a little girl who came to Dr. C. Fayette Taylor in December, 1874. She was then six years of age, and she had been taken ill four and a half years previously. During this time she had had severe gastralgia; an abscess had appeared in her right side four years before, and it was discharging at the time of examination. The patient's family history was bad. When first seen she was weak, pale, and emaciated; she suffered severely from gastric pains; she had been bedridden eight months, and there had been at times partial paralysis of the rectum and bladder; there was bilateral psoas and hamstring contraction, so that the heels touched the buttocks, and there were two marked projections, one from the fourth to seventh dorsal, and the other from the tenth dorsal to the second lumbar vertebra. It seemed probable that the entire spine below the neck was affected, and that suppuration was active—certainly about as unfavorable a subject as one could well imagine. The antero-posterior leverage support was applied at once with very marked relief. Soon after psoas abscesses appeared on both thighs, and the patient became anasarcous and had albuminous urine. She afterward began to improve, the abscesses alternately closing and discharging a little, until in 1878, and again in 1881, she walked for a time with crutches. In March, 1881, she was looking fat and well, and had been, for her, in excellent health for two years. In the spring of 1882, however, the patient assumed a waxy pallor, and was evidently failing rapidly. She died of exhaustion while in the country the following



[1] Read at the meeting of the Section on Orthopædic Surgery of the New York Academy of Medicine, held November 19, 1886.

July, undoubtedly with waxy viscera. The figures (A)[1] show the contour of the back before protective treatment was begun, December 3, 1874, and again on May 24, 1877.

It will be observed that in spite of the active and extensive suppuration going on, and the many unfavorable features of the case, no increase of deformity took place; on the contrary, both projections diminished considerably. To those who believe that the recumbent position will prevent deformity, I would state that this child sat up, crawled about the floor, and was taken out of doors before the last pattern was taken. There was no increase of deformity after this up to the time of her death.

Besides illustrating the fact that deformity may be arrested or prevented in a fatal case, we may infer from the one just cited that the progress of the curvature is not an accurate index, in all cases, of the state of the disease. We may see the disease getting better, or even well, while the deformity steadily increases: and we sometimes see the deformity arrested or reduced while the patient is really on the whole growing worse.

These statements regarding the prognosis of Pott's disease and its attendant deformity under mechanical treatment are the result of a study of these cases in the practice of Dr. C. Fayette Taylor and myself, and the cases cited, and to be cited, were treated according to the methods and principles advocated by him.

To sum up, our experience as to the deformity warrants us in expecting, on the average, to arrest its progress.

Before proceeding to the main object of this paper, the relation and discussion of certain exceptionally favorable, almost paradoxical, results, which have been observed and recorded from time to time in our practice, it seems necessary to say a few words regarding spinal mobility in Pott's disease. This is a large subject, worthy of separate and exhaustive treatment. I can only briefly indicate a few points.

In the irritative stages of the disease there is reflex muscular rigidity and consequent impairment of motion in the spinal column. When caries and ulceration take place the disks are compressed, and some of them disappear completely or in part, thus in addition organically limiting motion. True bony anchylosis is a much later and rarer event in Pott's disease, as well as in other joint diseases, than has usually been assumed to be the case. This is well shown by a study of the dorsal contours of a series of cases in all stages before and during suspension, such as will be found in Professor L. A. Sayre's report on the treatment of Pott's disease by suspension and the plaster bandage ("Transactions, American Medical Association," 1876), and in the work entitled "Spinal Disease and Spinal Curvature," published in 1877. It will be seen that the weight of the body during suspension produces a straightening that cannot well be wholly attributed to compensatory curves, and that presupposes motion through the diseased area in many even of the greatly deformed and long-standing cases, such as used always to be called anchylosed, and still are by many surgeons. Similar results can be seen after a voluntary effort to straighten, of which I show an example in these photographs.[2] In this instance the greatly deformed subject was able, while seated, to add voluntarily about an inch and a half to his height by simply making an effort to straighten up. Careful examinations by means of lead tracings taken under different conditions show motion in most of these old, so-called anchylosed cases, which is not easily explained by compensating curves. We have a large series of such tracings. It is easily seen that the spine straightens considerably, especially in acute cases, when the patient is placed on his face on a flat couch. I show two patterns (B) of a recent case, taken before treatment was begun, the one after the child had lain on his face for about an hour, the other a few days later,[1] when the child was sitting up. A larger part of the change is above and below the affected vertebræ. The patterns of another case (II.) before treatment show motion at the point of disease. We usually find the spine mobile to some degree in old as well as recent cases, and many patients are cured with motion through the affected vertebræ. I have a considerable amount of evidence in support of these assertions in my possession, but have not space to submit it here, nor do I wish at this time to discuss the questions raised by the foregoing statements. I merely deduce two propositions that have a more immediate bearing on our present study.

B

1. The position of the patient is of considerable importance where patterns of the back are taken for record and comparison.

2. Many years must be allowed to elapse before ultimate results as to deformity can be studied and recorded, since in the absence of anchylosis, even if caries is cured, the new tissues may yield and a gradual bending take place.

This latter proposition has unfortunately been verified several times in our practice, when patients insisted on discontinuing support too early, not being able to comprehend its necessity in the absence of symptoms. A gradual and considerable increase of the projection resulted in several instances, sometimes without any recurrence of other local or constitutional symptoms.

I wish to call attention in connection with the cases of recession of deformity, which I will now proceed to relate, to the length of time many of them were under observation, and especially to the length of time which had, in several instances, elapsed between the date of discontinuance of treatment and the last examination.

The patterns were taken by means of a flexible lead strip, which, after being accurately fitted to the back, was traced on card-board and the tracing cut out. Great pains were always taken to have them accurate, the pasteboard pattern always being applied to the back to see that it actually did fit before it was accepted. As the patient is never allowed to sit or stand without the apparatus, while there is any disease, the first patterns are always taken with the patient in the prone position on a hard, even couch. After the cure the pattern is sometimes taken with the patient sitting, so that the conditions of posture are those least favorable to improvement in outline.

Case I.—The patient, a young girl, was first seen in December, 1864, and was then about thirteen years of age. She was bedridden and had been given up to die by her physicians and friends; there were abscesses either side of the lumbar vertebræ, and over the crest of the ilium, discharging pus and pieces of bone. The application of protective apparatus was followed by prompt relief of symptoms, and the disappearance of the deformity in the dorso-lumbar region, which was considerable, as shown by the pattern.

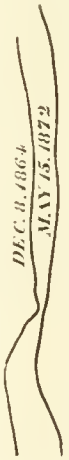


Fig. 1.

An outline taken in May, 1872, five and a half years after the beginning of protective treatment, showed a mere trace of the deformity. The patient was then in rugged health and actively devoted to society, horseback-riding, etc., without fatigue: in fact, she felt so well that she had not reported with sufficient frequency at the office. In 1877 she still wore the apparatus as a protection, and an abscess on the left side, above the crest of the ilium, was still discharging. This patient married and had one child. I have recently heard through a relative that she continued in fair health until about a year ago; since that time she has been seriously ill, and a few days ago I heard of her death, but I have not been able to learn the particulars.

[1] The patient faces to the left in all these profiles.
[2] Shown at the meeting of the Section.

[1] The date of the pattern taken sitting should read October 21st.

Case II.—A delicate girl, aged eighteen, subject to headaches, applied for treatment in January, 1865. She had complained of pains in the stomach for several years, and had a knuckle in the lumbar region of the spine. This patient wore the spinal apparatus and progressed favorably. All the symptoms and the deformity disappeared. The apparatus was removed in 1871, and the patient soon after married. She was seen by me in March, 1886, having been in perfect health since her discharge, and was an unusually strong, in fact robust, woman, and had, clothed, no trace of the disease or deformity. She has five healthy children. Her patterns, taken in 1877, six years after discarding the support, show flexibility of the spinal column, and no deformity. (See Fig. 2.)

Fig. 2.

Case III.—This patient came in January, 1865, aged three years and nine months. The disease had existed eighteen months, and was located at the eleventh dorsal to the second lumbar vertebra. When presented he could hardly walk. There was immediate and great improvement following the application of the apparatus, the patient walking erect with ease, and considerable recession of the projection soon followed. He continued very comfortable until October, 1865, when abscesses appeared on both sides and in the left groin, followed by extensive sloughing and penetration of the peritoneal cavity. During the following winter the patient's condition was bad, but in July, 1868, he had improved very much, the abscesses had contracted and discharged less, the appetite was good, and his prospects of recovery were considered encouraging. During this time the curvature had markedly diminished, and it continued to straighten until the last pattern was taken, December 7, 1868 (Fig. 3); but there was evidence of the disease appearing three vertebræ higher up. There is no record after this, and I do not know the ultimate result.

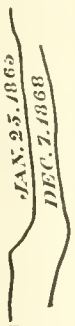

Fig. 3.

Case IV.—The patient, a delicate boy, five and a half years old, came, April 8, 1869, with slight prominence of the lumbar vertebræ, and a bad tilt to the left. He had fallen down-stairs in the August before, and the shoulders began to be elevated soon after. The mother had noticed the spinal curvature only five weeks. The patient had complained of being hurt on coughing, and had pains in the chest and abdomen at times; he breathed badly and was easily tired. A spinal apparatus was applied April 10, 1869, and the patient did well. In 1873 his health was excellent, though he still leaned to one side. In August, 1876, the patient reported in excellent health. He was nearly thirteen years of age, fifty-eight and a half inches tall, and had not worn the brace for several years. The patterns (Fig. 4) show that the slight deformity had disappeared.

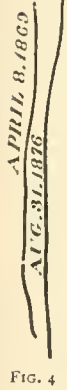

Fig. 4

Case V.—A little Cuban girl, of three and a half years, with disease of the lumbar vertebræ—probably of traumatic origin—psoas contraction, gastralgia, and an abscess to the left of the projection, was brought, unable to walk, February 26, 1870. The projection was first noticed by the mother three months previously; there was no phthisis in the family. Protective treatment was begun at once. December 24, 1870, an abscess was opened on the right side. On June 21, 1871, the abscesses were closed, the psoas contraction had disappeared, and her health was good. In spite of an attack of intermittent fever, contracted on Long Island in 1872, the patient seemed to be (March, 1874) in perfect health, and there had been no symptoms of vertebral inflammation for over a year. The patterns show marked straightening, at the point of disease, from June, 1871, to May, 1873. The pattern taken in 1873 fitted exactly in December, 1876; the one taken March, 1877, showed considerable further improvement. In February, 1878, the patient seemed cured, and was well formed and developed, but it was deemed advisable to continue the use of the apparatus and increase the pressure, as a slight lateral deviation of the spinal column, which had always been present, seemed more marked. The pattern taken in December, 1879, showed a further slight improvement in the deformity (Fig. 5). On May 12, 1880, the patient was thirteen and a half years old, fifty-seven and a quarter inches tall, and in remarkably good health. This patient's mother wrote recently that her daughter was in perfect health.

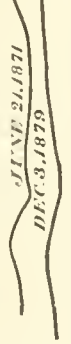

Fig. 5.

Case VI.—A girl, eight years of age, a native of Cuba, came in August, 1872. The relatives were healthy, and there was stated to be no phthisis in the family. A mild attack of measles had occurred two years previously. In May, 1871, while in excellent health, the patient was taken with a severe paroxysm of pain in the right side, accompanied by very difficult respiration. These attacks began without apparent cause, and continued at intervals until the August following, when they disappeared after electrical treatment. Since then the paroxysms had ceased, but pain in the side was provoked, whenever the patient received a sudden jar, up to the date of examination. At about the same time a peculiar gait (shrugged shoulders and contracted chest) was noticed, which has continued. In the spring of 1872 the patient had a severe fall over the balusters, and at that time the projection of the back was first noticed. At the date of examination the patient's health was beginning to fail, there was slight left psoas contraction, and pain in the side. The contour of the back is shown in the pattern (Fig. 6). The spinal apparatus was applied August 12, 1872. The patient was relieved of pain in the side after the first night. In spite of too irregular attendance (the patient being in a convent), and an attack of diphtheritis, with partial paralysis of the left forearm and the muscles of deglutition, in the spring of 1873, the patient did well. On April 22, 1873, hard pads (horn) were substituted for the soft ones on the apparatus. On October 6, 1873, Dr. C. Fayette Taylor predicted recession of deformity, and modified the apparatus so that there was more pressure on the lower part of the projection. In October, 1873, the patient complained of pain on the inside of right thigh. Slight psoas contraction was discovered, and the probability of abscess recognized. On November 25, 1875, very marked diminution of the projection was noted. The patient's health was excellent. The alarm excited two years before by the psoas contraction has procured greater care on the part of the mother. September, 1876, health excellent; contour of back perfect. Apparatus removed in April, 1877. This patient was seen several times in the spring of 1883. She was of the ordinary stature, and her figure and health were perfect.

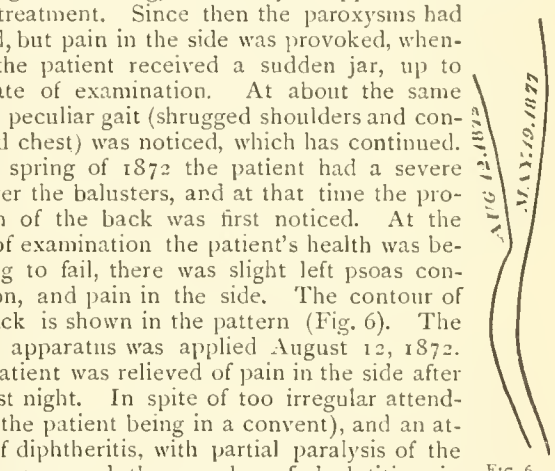

Fig. 6.

Case VII.—A boy, five and a half years of age, came June, 1873. Examination showed a considerable kyphos in the mid-dorsal region of the spine, seen in the tracing (Fig. 7). Two years before he had had a fall, striking on the buttocks; a knuckle was noticed a year previous to coming. His general health was delicate; he had had suppuration of the cervical glands at seven or eight months of age, and had been troubled with imperfect digestion. He suffered no pain, except at times in the stomach, after a passage from the bowels. No apparent abscess and no paralysis. Slight right psoas contraction. Family history good, so far as ascertained. The patient walked at twenty-two months. Protective treatment was begun at once, and was kept up until 1878—five years. The

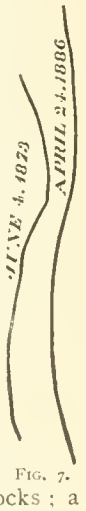

Fig. 7.

deformity, which had been considerable, completely disappeared during the first year of treatment, and never recurred. This patient has been seen frequently since his discharge, and maintains perfect health; there is no deformity, and but a slight stiffness at the previously diseased focus. In April, 1886, this patient was eighteen years old, and had not worn any apparatus or received any treatment whatever for the back for eight years; his figure and health were perfect. Chest: expiration, thirty-three inches; inspiration, thirty-six inches. Height, seventy inches in stocking feet; and weight, one hundred and forty-three pounds. The spine was normal and flexible. The patient could bend easily forward, and to both sides, some stiffness at the old focus being the only remaining trace of his disease.

Case VIII.—A little girl, five years old, came in March, 1875, with disease of the tenth to twelfth dorsal vertebræ. Pain in the sides and stomach were noticed in October, and the projection, in the December preceding. She had had a wheezing respiration, and had been sickly for three years; she had previously been very healthy. She still suffered at the time of application from gastric pain, and there was a right psoas contraction. The apparatus with hard-rubber pad-plates was applied in March, 1875. The patient did well; the acute symptoms were promptly relieved, and the deformity, after increasing some, diminished a good deal. All treatment was discontinued in December, 1884, the patient having been well for some time, but wearing the apparatus to prevent yielding of new cicatricial tissues. The patterns (Fig. 8) show the course of the deformity. The last one was taken in May, 1884. I have heard that this patient has remained well, but have not had an opportunity to examine her recently.

Fig. 8.

Case IX.—The following case illustrates not only very remarkable rectification of deformity, but restoration to health in a case where the constitutional symptoms were so severe as to make it seem almost hopeless. The little boy, six years of age, was brought with disease of the lower lumbar vertebræ, and very considerable angular deformity, in March, 1884. The parents dated his trouble from the previous July. In December an abscess broke in the left groin, which was still discharging freely at the time of the examination. The patient was of waxy hue and cadaverous appearance; he could neither stand nor walk; ate very little; right psoas contraction; skin dotted with pustules; pain at sides, and at times could not be stirred. The patient lay in bed with the limbs flexed, not attempting to move, and hardly able to speak—the sickest-looking child, but one, I ever saw. The spinal apparatus was applied April 8, 1884. The patient's temperature was taken frequently, and he was found to have a fever, running up to one hundred and two degrees in the afternoon. After the apparatus was well fitted this disappeared, and the patient seemed much brighter. At the end of a month he was taken home, and returned in June in a poor condition. He was very weak, and there was a fluctuating swelling over the right side of the sacrum, and extending over the right ilium, and up into the lumbar region. This was incised, and much thick pus evacuated. After this, another incision was made higher up, and a spontaneous opening appeared still higher. The three openings soon coalesced, leaving a large granulating aperture. All this time the patient was doing well, and the deformity was beginning to recede rapidly. He began to walk the last of July, 1884, four months after beginning treatment. After returning from the mountains, in September, he weighed forty pounds. He walked easily and stood upright. He was also able to lie flat on his face, which he never could do before, only slight contraction of the right psoas remaining. The patient continued to improve in every way, recovering good color and appetite, and becoming quite active. The parents discontinued treatment, contrary to advice, in 1885. When last seen, in May, 1885, the abscess in the groin was still discharging moderately, and the one behind only a very little from a small opening. The patterns show the change in the deformity (Fig. 9).

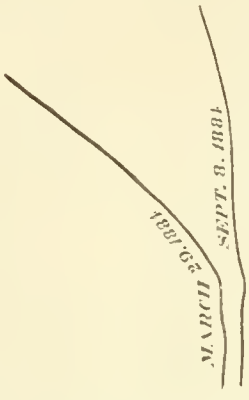

Fig. 9.

The foregoing nine cases have been selected from our notes solely with reference to the study of the decrease of deformity which they have exhibited, and which has been carefully recorded by means of their patterns. They do not comprise all, even of the marked examples, as I have not made a systematic search through our records, but have merely taken such cases as I knew of or chanced to find, and have omitted several good examples because the history or patterns were wanting. I have personally seen and studied, according to my opportunity, seven cases of the nine. They are certainly exceptional, and not ordinary results.

Their histories show that most of them suffered from advanced disease of severe grade before they had mechanical treatment, and in several the deformity was very considerable, representing a good deal of tissue-destruction. Suppuration, appearing externally, and psoas contractions were the rule. The disease was located, in all but one or two cases,[1] below the middle of the back. Positive progressive straightening at the kyphos is not doubtful in most of the cases, and in numbers it has been proved to be permanent, and not temporary. Whatever the explanation of these facts, this straightening is something more than the rounding off of sharp projections, which usually occurs when a vertebral caries is healing. Secondary or compensatory curves are seen in some of these cases, but are not competent to cause the change at the focus of disease.

I think that these cases furnish strong evidence, if such were needed, that Dr. Taylor's spinal apparatus is capable of relieving the diseased bodies of the vertebræ of pressure, as it is inconceivable that the gelatinous new tissues of healing should wedge apart the bodies of the affected vertebræ, and thus straighten out the projection. The distances between the spines was marked off on several occasions in cases of total recession, and seemed to show that there had been longitudinal condensation, which implies a sliding upon each other of the articular facets. So that these patients, even when the deformity has totally disappeared, have probably slightly shortened backbones.

I had the opportunity, last spring, of assisting at the autopsy of a patient of Dr. Seguin and myself, who died from a cancer of the spinal column, apparently originating in the body of the first lumbar vertebra, which had almost entirely disappeared. There must have been a longitudinal condensation in the spinal column of at least half an inch, and probably more; but there was no knuckle or kyphos of the lumbar spine, though there was rigidity and the normal lumbar curve was obliterated.

In concluding I would express the hope that the discussion may clear up many points in regard to recession in Pott's disease, which I am conscious of having imperfectly presented, and especially that it may show us how this desirable result may be more frequently attained.

Druggists.—A druggist is not inappropriately termed the pill-ar of society.—*Exchange.*

[1] Since writing this paper I have found another good case of recession in the mid-dorsal region.

DO ANTIPYRETICS AS AT PRESENT EMPLOYED MODIFY THE DURATION OR MORTALITY OF TYPHOID FEVER?[1]

By S. BARUCH, M.D.,

PHYSICIAN TO THE NEW YORK JUVENILE ASYLUM.

If we appreciate the enormous mortality of typhoid fever, as gathered from the reports of our city Board of Health, we must acknowledge that this disease is a scourge in New York City. Through the kindness of Dr. Nagle I am in possession of the statistics of cases and deaths reported during the past ten years—from 1876 to 1885 inclusive. These offer the following startling figures: 7,712 cases and 3,184 deaths, or an average of 41.28 per cent. of mortality. And during the present autumnal season, viz., from September 1 to December 16, 1886, the cases reported are 527; the deaths, 183; showing the enormous mortality of 34.68 per cent. These being stern facts, is it not high time that the profession should awaken to the magnitude of the question propounded for discussion to-night: "Do the antipyretics as at present employed modify the duration or mortality of typhoid fever?"

Referring to the statistics obtained from Dr. Nagle, it would appear that many of us are at this very time daily confronted with the burning question of treatment. It will therefore be of immense value to ourselves, and more especially to the large number of those who are to-night languishing with this slow, insidious, and treacherous disease, if we can contribute something to their relief and ultimate recovery, by our discussion of this subject of antipyretics.

Let us approach it, therefore, with a full sense of our responsibilities and a correct appreciation of its solemn magnitude.

In response to your request, Mr. Chairman, I will briefly outline my personal experience regarding this vital question, referring at the same time to what I regard as the ideal antipyretic therapeutics of the present time. This succinct clinical statement of my position will, I trust, introduce the subject.

Unfortunately for the calling to which we have devoted our lives, our therapeutic problems can never be demonstrated with that mathematical precision which true science demands. The premises of the problems presented to us for solution are, as we all know but too well, so unreliable, variable, and occult, that, after all, we are relegated to an enlightened empiricism in our therapeutics of disease. Even in typhoid fever, a disease which is so prevalent as to be constantly under observation in all parts of the world, under all conditions of temperature, climate, age, habit, and environment, the treatment has not yet reached a satisfactorily settled position in the minds of the profession.

The first improvement in typhoid-fever management resulted from the idea that it is a self-limited disease, with a tendency to prostrate the vital powers. This idea came during what I term the renaissance period of medicine, that period which was signalized by the abandonment of violent efforts to throttle disease by active medicinal incursions upon the system, and by the substituting in their stead a wise observation of the conservative tendencies of the natural powers as exemplified in the development and maintenance of the human body in health and disease. In following the guidance of nature the expectant method of treatment was developed, with the result that the mortality was at once reduced.

But as in the treatment of other acute diseases various remedies still remained in vogue whose mildness did not forbid their application, and whose action was in the direction of a favorable influence upon the comfort and well-being of the patient, and thus aided in the maintenance of his vital powers, so was developed a treatment of typhoid fever whose aim it is to improve upon the purely expectant plan. Extremes of the latter have come to be viewed with as much suspicion as extremes of the former active medication. The sins of omission in the one are as reprehensible as the sins of commission in the other. Why is this question of antipyretics before us to-night? My answer is that the extremists of this new, active therapeusis have brought this valuable method into disrepute, so that even in Germany, the nursery of active antipyresis, the profession has called a halt, and is pausing ere it continues to rush headlong in the wake of Brandt's extreme cold-water or Liebermeister's quinine treatment. A recent cartoon, evidently drawn by one of Berlin's medical artists, ridicules the extremely expectant and antipyretic wings of the profession, and, as the well-conceived work of the humorous pencil usually does, brings the idea home to the observer. He represents two patients lying ill of typhoid in a hospital. One of these is surrounded by a number of physicians, who, with anxiety depicted on their countenances, are introducing thermometers into the mouth, axilla, and rectum, while near by stands the hydropathic paraphernalia, Brandt, and Liebermeister. The other patient is calmly lying upon his couch, while upon a distant cot sit the expectant doctors, with legs crossed, puffing cigarettes, and complacently watching with serene countenance the progress of the sufferers. Let us avoid both extremes. It has been carefully noted, and evidence continues to accumulate to establish *as a fact*, that in typhoid fever there are several indications to fulfil. Old Professor Schoenlein used to say there is an indicatio causalis, an indicatio morbi, and an indicatio symptomalis to guide the physician in the treatment of all diseases. If we could remove the indicatio causalis and neutralize the etiological factor of typhoid fever, we would accomplish a truly scientific feat. But although we are not without hope in this direction, the day still seems far off ere such a consummation will be reached. All that we may do, therefore, lies in the direction of the indicatio morbi et symptomalis.

The elements of danger which threaten our patient have been well ascertained to be: First, hyperpyrexia, which jeopardizes the heart-muscle and induces great depreciation of the entire muscular system by the excessive oxidation, to which it is partly due. Second, failure of the vital power through the enfeebled condition of the digestive and nutritive processes. Third, the immediate and remote results of the local gland-lesions.

I hold that the physician who clearly recognizes and has steadily in his mind's eye these ever-present dangers, and who endeavors to arm himself with means to avert and neutralize them, will attain to the most successful results in his treatment.

I hold that the first and most threatening of all perils in typhoid fever is heart-failure. So long as the cardiac sounds are clear, the impulse at the apex distinct, and the pulse-wave resisting, so long, we all know, there is a good prospect for our case.

Let the temperature be what it may, with a good heart we expect to carry our patient through safely. A good heart is to the physician in typhoid fever what a stanch ship is to the mariner in a storm. Let us, then, do all we may to preserve the integrity of that organ, upon which so much depends. I say to *preserve its integrity* advisedly, for while we may not need the strong heart during the first days of the fever, the day will come when we will call upon Hercules to help us, and woe betide our patient if we *then* call in vain, if we *then* discover too late that the golden moments for storing up reserve forces in the heart have slipped from our grasp. The first weeks offer an opportunity for providing against the day of need, which will almost surely come in all cases in which a high temperature has prevailed.

I hold that we possess, in a judicious selection and application of the antipyretics at present employed, a therapeutic resource which preserves the heart and muscular

[1] Read before the Section in Practice of Medicine of the New York Academy of Medicine, December 21, 1886.

system for the struggle which will be thrust upon the patient. Some hold to the view that stimulants administered in the beginning of the fever process tend to conserve cardiac energy; but this idea has been proven erroneous. Stimulants afford a spur to the heart when already enfeebled and laboring under stress of typhoid fever. They are as valuable at this time as they are injurious in the early days of most cases.

We know, however, that a continuous high temperature imperils the heart, and disables it from coping with coming emergencies. By reducing this temperature to a reasonable limit, the danger is diminished. A temperature of 102° or 103° F. is not fraught with danger; on the contrary, the fever process is a conservative effort of nature, it should not be violently interrupted. But when the temperature rises to 104° and over, and so continues for many hours without falling below 103°, at last there is danger to the heart. It must be reduced at once. If this rule be applied in the early days of the case, I have no doubt that the course of the disease will be favorably modified.

I do not favor very cold baths nor large doses of antipyrin (these being our safest antipyretics at present). Just enough antipyresis to bring the temperature for five to seven hours below the danger point, is urgently demanded. It is an error of frequent commission to regard a temperature below 103° as dangerous and to intercede for its reduction. All that is necessary is to *curb the pyretic tendency* and leave the rest to that good old handmaiden of the doctor, the *vis medicatrix naturæ*. Not many years ago, when high temperatures were first ascertained to endanger the heart, all considerable elevations were regarded askance, and then a false idea became prevalent, resulting in the present depreciation of antipyretics. To stem the tide which is now running in the opposite and surely dangerous direction, I beg to raise a voice of warning to-night. There is need for a pause of reflection. Many friends whom I meet in consultation or discussion are becoming sceptical regarding the benefits of antipyretic remedies. Some have been too enthusiastic on the subject, and are now in the stage of depression; others delight in a therapeutic nihilism and are happy to say: "I told you so, it is useless to administer medicines in typhoid fever; it is a self-limited disease, let it take its course; examine for the bacilli, cultivate them with diligence; then be sure to make the post-mortem, and you will find the diagnosis confirmed." This is true science, they say! But what good does this scientific method afford to the patient. He wants to be cured, he does not want the bacilli cultivated, but his vitality maintained, his temperature reduced, his sleep secured, and his ulcers healed. And this brings me to another view of this question.

Experience teaches that in the treatment of all diseases of any duration, it is of immense importance to bend every effort to secure for the patient as nearly a normal condition as is possible. In other words, the more comfortable we can make him, the more sleep we secure for him, the more naturally his secretions are maintained, the more surely is he to recover. Now, we have in the graduated Ziemssen bath and in the more recently introduced antipyrin, safe and certain measures to reduce the high temperature, which not only jeopardizes that fountain-head of all his strength—the heart—but which also renders him thirsty, wakeful, restless, and altogether miserable. We reduce a temperature of 105°, by moderate doses of antipyrin and cold sponging, to 102°, the patient perspires, the pulse softens, the tongue becomes moist, the kidneys act better, and altogether our patient expresses himself as more comfortable. Is this not an important factor in carrying the case to a successful issue?

From what I have briefly said it will be gathered that while I do not believe that the duration of typhoid fever can, to any great extent, be shortened, nor relapses or complications avoided by the use of antipyretics, I do believe that its course may be decidedly modified and the mortality reduced. Careful study of this subject during the past ten years, and comparisons with my results during the preceding fifteen years, have left this impression on my mind, until it has become a fixed conviction. To cite statistics from my own observation would accomplish but little, for it requires a very large number of cases to reach a conclusion upon this point.

We must therefore come back to an empirical knowledge, deduced from repeated and careful observation of cases in their various phases.

A few words more on the subject of "antipyretics as at present employed," and I have done. This should be an important element of our discussion to-night. The idea that the secondary effect of antipyretics is depressing to the heart, has been urged as a serious objection to their employment. This is true of large doses of these remedies, as it is true of inappropriate doses of all valuable remedial measures. The sudden submergence of a typhoid patient with a temperature of 104° into a bath of 60°, several times a day, according to Brandt, may not weaken a German soldier, but it is not so well adapted to an American constitution, if we may judge from our own hospital reports. At any rate, this heroic treatment has not found favor in our hospitals.

We have come to recognize the fact that a rapid and sudden reduction of temperature, from 104° to 99°, is not necessary at all, even if it be not a dangerous measure. All that is required is to bring the temperature down below the danger-point, and keep it there for four to six hours out of the twenty-four. This may be accomplished by cold sponging and cold wet compresses over the larger part of the anterior portion of the body, without disturbing the patient very much. Indeed, these are so grateful to him that he rarely objects to them. By this means the temperature may be almost invariably brought down one or two degrees, and held at this point for a few hours. If it be necessary, however, to make a more rapid impression in cases of very high temperatures, the graduated Ziemssen bath may be resorted to with advantage.

To a patient with a temperature of 105°, water at 95° will feel rather cool, and afford sufficient shock to the nervous centres to arouse them. The extremities are kept out of the water as much as possible, and chafed if cool; ice-water is added near the neck of the patient, and by rapid stirring the temperature of the bath is reduced to 80°. The pulse is watched, and a thermometer in the mouth will indicate when a reduction to 101° has been attained. The patient is now wrapped in a linen sheet, his extremities enveloped in flannel, and a wet compress laid upon his abdomen. The result will be an almost certain reduction of temperature for several hours. If the nervous centres are overcome, and stupor is present, a more sudden cold immersion will be of great value, and often accomplish more than the mere reduction of temperature or stimulants can do.

In a large proportion of cases, however, the bath is not required, especially as we now have in antipyrin a safe, reliable, and rapid antipyretic. It is my practice now to prefer antipyrin to the bath, unless there be considerable disturbance of the nervous system, with sleeplessness and delirium.

And here again it should be urged that the heroic doses prescribed by the gentlemen who introduced antipyrin are entirely unnecessary. Doses of thirty grains repeated hourly until the temperature be reduced to 100°, I have never resorted to. Hence I have never seen cases of collapse. A dose of twenty to twenty-five grains for an adult, repeated in an hour if the temperature has not begun its downward course, will accomplish all we require for the safety and well-being of our patient. Bring the temperature to 101° or 102° for four or five hours, and the pernicious effect of a continuous hyperpyrexia on the heart will be stayed. The later stages of the disease will afford valuable evidence of this antipyretic

effect, inasmuch as the heart will respond to stimulants when it begins to flag, during the third or fourth week.

A recent case, in which I had the pleasure of being associated with our chairman, demonstrated this effect of antipyrin. A boy, seven years of age, came under my care during the second week of typhoid, with temperatures ranging daily to 104°, which were reduced by five- and seven-grain doses of antipyrin. He passed favorably through the fourth week; temperature became normal and remained so three days. Peritonitis now ensued, during which five grains of morphia in the course of twenty-four hours were administered hypodermatically, without the slightest effect upon the agonizing pain. Morphia was stopped, and one-fourth grain calomel administered, and two drachms of mercurial ointment rubbed into the arms and thighs. The bowels moved, distention subsided, pain was subdued, patient fell asleep, and the temperature became normal. Two days were passed in comfort and hope, but now the evacuations pointed to deep ulcerations with hemorrhage. Various remedies and articles of diet were tried, until barley-water alone was given, when the mucous and bloody stools ceased at once. Now the temperature rose suddenly, with chattering of teeth, to 105°, and fluctuated to 106° constantly. A severe chill occurred on the day previous to his death, which was due, I believe, to hepatic abscess. Even in this depressed state, three-grain doses of antipyrin reduced the temperature two degrees, and the pulse became more full during the lowered temperature period. The chief point I desire to emphasize is the fact that during all these trials, lasting two and a half months, the pulse often failed, and even became so rapid as not to be counted; but stimulants always brought it up, making it slower and steady, so that, even twelve hours before his death, the pulse was steady and not very compressible at 150.

This case clearly demonstrated the saving effect of temperature reduction in the early stages, and the advantages gained in emergencies which may follow from a well-preserved heart; while at the same time it points to the fact that antipyrin does not prevent complications or sequelæ.

To summarize, then, I would say that a proper use of antipyretics modifies the course of typhoid fever and diminishes the mortality, because it diminishes the chief danger—heart-failure—and because it enables us to render the patient more comfortable, and therefore more quiet and tractable.

43 East Fifty-ninth Street.

Paris Hospitals a Century Ago.—The celebrated Hôtel Dieu, in Paris, only about one hundred years ago presented many features consistent neither with humanity nor the most rudimentary hygiene, as we understand the subject. A humane law forbade the hospital to turn away any patient seeking admission; but the law, apparently, did not insist upon the provision of the necessary space. The whole establishment covered only about three acres, and within this area there were crowded at one time over five thousand sick and injured people. It was computed that, without allowing anything for staircases, passages, and offices of various kinds, there must have been a sick person in every floor-space of thirty feet, right throughout the hospital—every floor-space seven feet and a half long and four feet wide, that is to say. A large proportion of the beds were intended to hold four people, and into these six patients were frequently crowded. It is said to have been no unusual thing for two or three small-pox patients to have been huddled into a single bed, and as many as four women in childbirth were thus laid side by side. Indeed, if some accounts may be relied upon, things were at times far worse than this. The hospital seems to have been adapted only for times of normal public health. Any outbreak of epidemic disease crowded the place to a frightful extent.—*The Hospital.*

THE TREATMENT OF HERNIA BY SUBCUTANEOUS INJECTION.[1]

By W. B. De Garmo, M.D.,

instructor in the treatment of hernia at the new york polyclinic.

It has been said that our present method of treating hernia by subcutaneous injection is old; that it had been thoroughly tried, found wanting, and discarded years ago.

Before considering the results of the method as now used, I shall attempt to prove, by the literature of the subject, that this criticism is unjust, and not founded upon fact.

The history of subcutaneous injection begins with Velpeau, who in 1840 published[2] what he termed a new operation for the cure of hernia.

It was performed by making an incision with a bistoury through the integument and subcutaneous fascia to the hernial sac.

The sac was then opened just enough to admit the nozzle of a syringe, and from one-half to one drachm of tincture of iodine was injected.

This was done with the view of exciting an inflammation which should obliterate the hernial sac in the same manner that hydrocele is sometimes cured.

At about this time Dr. Pancoast was experimenting in the same field, and in his "Operative Surgery"[3] published in 1844, he claims to have used his operation for eight years, and with considerable success.

He passed a small trocar *into* the hernial sac, and with the sharp point of the instrument scarified its inner surface.

The trocar was then withdrawn from its cannula, and half a drachm of tincture of iodine, or an equal quantity of the tincture of cantharides, was injected.

The year previous to the publication of Dr. Pancoast's work, Heaton had published an article in the Boston *Medical and Surgical Journal*,[4] in which he claimed a new method of treating hernia.

After some commonplace remarks he says: "In order to excite the necessary irritation in the parts immediately concerned, I inject, with a very delicate instrument invented for the purpose, an exciting fluid."

He does not state what the fluid was, nor does he describe the instrument used further than stated in the paragraph cited.

In later numbers of the same journal,[5] from 1843 to 1847, he gives reports of cases cured, as he claims, but fails to make known the details of his operation.

At this period Heaton, deservedly, had some bitter opponents; but even those who denounced him in the strongest terms admitted that he was curing some of his cases of hernia, while most other operators were meeting with almost constant failure.

In 1850 Dr. H. G. Bigelow[6] advocated the treatment of hernia by injection of iodine into the hernial sac. Careful review of his writings at this time leaves little doubt that he thought that Heaton was doing the same operation.

One year later Dr. J. Watson[7] speaks with indignation of the man in Boston who had not made known his method, but admits that one of his own patients had been cured by him.

Dr. Watson determined upon doing what he believed to be essentially the same operation, although he deemed it safer to cut down to the sac than to attempt to reach it with a trocar.

Accordingly he opened up the parts and injected tincture of cantharides into the hernial sac. His patient was not cured, but some improvement was claimed.

In 1852 a committee appointed by the American Medical Association to inquire into the best methods then in use for the treatment of hernia reported as follows :[1]

"I. That there is no surgical operation at present known which can be relied upon with confidence to produce in all instances, or even a large proportion of cases, a radical cure of reducible hernia.

"II. That they regard the operation by injection by the subcutaneous method as the safest and best. This will probably in some cases produce a permanent cure, and in many others will afford great relief.

"III. That compression, when properly employed, is, in the present state of our knowledge, the most likely means of effecting a radical cure in the greatest number of cases."

This committee called upon Heaton to disclose his method, but failed to obtain any information from him.

In 1854 P. Ricord[2] devised a long trocar especially designed for injecting the *interior* of the hernial sac. The following year Nélaton[3] published what he termed his modification of Lecocq's trocar for the same purpose.

This brief review completes the literature of the subject until as recent a date as 1877, nothing of consequence having been written between 1855 and that date.

A most careful study of the subject proves that all modifications of the operation were directed toward the destruction of the hernial sac, and that all instruments devised only sought to aid in accomplishing this end. The substances introduced—cantharides and iodine—were those calculated to produce an inflammatory action. This error of considering that to the presence of the hernial sac in, and protruding through, the inguinal canal, is *wholly* due the recurrence of the hernia, is one that has repeated itself age after age.

Early in the present century Sir Astley Cooper and William Lawrence, doubtless the most eminent authorities on hernia who have ever lived, demonstrated that the destruction of the sac was not absolutely essential to the cure of the hernia. Notwithstanding this fact nearly every operator has seemed to be thoroughly impressed with the idea that no cure could result unless this end was attained. It is quite certain that those writers already cited in connection with the early history of subcutaneous injection had that object, and apparently none other, in view. In 1877 a new era was opened in the subcutaneous treatment of hernia by the publishing of the methods which Heaton had been using from 1843 up to that date. It was shown that the operation was founded upon principles entirely at variance with those which had been indorsed by Velpeau, Pancoast, Ricord, Watson, and others.

He made no attempt to destroy the hernial sac, his fluid was not one intended to produce an inflammatory action; in fact, against the latter condition he carefully guarded. The whole intent of the operation was to so fortify the fibrous and connective tissue surrounding the canal that a protrusion would not occur. Had it not been for the death of both Dr. Heaton and the able editor of his book, Dr. J. H. Davenport, within a few months after the issue of their work, doubtless much additional light would have been thrown upon this operation.

As it was, however, it was left in the hands of the profession, complete as regards the method of operating, but lacking in many of those practical points which an almost life-long experience could have furnished. As a matter of fact the Heaton method stands alone. It differs in every detail from previous methods of subcutaneous treatment. The fluid used acts primarily as a strong astringent, and secondarily as a mild but persistent irritant. This action is upon the muscular and tendinous structures of which the canal is formed, and upon the connective tissue which binds its various layers together.

Wood, in speaking of the inguinal canal, says :[1] "It is closed in a valvular way by the close apposition and areolar connection of the deep and superficial walls or boundaries. This adhesion by connective tissue is torn or stretched in the formation of a hernia, . . . and it is one of the most important objects of a radical cure of hernia to restore this adhesion and reinstate the valvular action of the walls of the canal, if possible." To accomplish this Mr. Wood has for many years advocated his method, which he calls subcutaneous, of bringing the walls of the canal into apposition by loops of copper wire introduced through a small aperture in the scrotum. Mr. Spanton[2] has attempted to obtain the same result by the use of what he calls his corkscrew instrument, this also being called a subcutaneous method. The result in both of these operations, however, depends upon an inflammatory action which may at any time exceed its intended limits, to the very great risk of the patient's life.

That the necessary restorative process can be established, and a favorable result obtained in many instances by the white oak-bark injections, I have had sufficient evidence to convince me, and that this is accomplished without risk to the patient is equally certain.

Seven years ago[3] I made a plea for the fair trial of this operation, which at that time, and for reasons then stated, was being neglected by the profession.

In my indorsement of the method I was at that time almost alone; but since then the medical journals bear testimony of its indorsement by Powell,[4] Phillips,[5] Heath,[6] Bull,[7] Hand,[8] Gay,[9] Bennett,[10] A. M. Vance,[11] and many others.

Eminent surgeons, who were its opponents, are now teaching it in their clinics, and are strong in their approval of the method.

That frequent failures have occurred is beyond question.

To throw light upon the cause of some of these failures, and call attention to some of the errors which have led to them, is one of the objects of this paper.

After nearly ten years' experience with this operation we certainly ought to be able to assign it to its true place among our aids in the treatment of hernia.

Too much was expected of this operation by many of those who have undertaken to use it, and this was in a great measure due to the manner in which Heaton placed it before the profession.

It was quite natural that, with his cases in a private hospital, under his immediate control, and with an experience extending over many years, he should meet with greater success than could the general operator.

He makes no allowance for this in his writings, and for this reason alone some physicians have been disappointed in the results which they have expected to obtain.

Then, again, it has been put to unfair tests, as in the following instance, which occurred in one of our leading hospitals. The injection was made in a proper manner

we will assume, and the patient kept in bed for about one week. At the end of this time the man was placed upon his feet and requested to cough and strain, in other words, to force his hernia down if he could. It is needless to say that the patient's efforts were attended by success, and the operation was credited with failure. I speak advisedly when I say that there is *no* operation for the relief of hernia, at present known, which would stand this test. It is irrational to suppose that pathological changes which have been months, or even years, in developing, can be removed radically within a few days by a process which is so mild in character as the one under consideration.

Another error has been in operating upon old scrotal hernias, where the hernial sac and surrounding tissues are thickened and changed in character, anticipating a radical cure by a single injection. We must either modify the operation by repeated injections and longer confinement to bed, or exclude such cases altogether. It must be borne in mind that in these old neglected cases we have not only the dilated, shortened canal and thickened sac, which are predisposing causes to the recurrence of the hernia, but we have a funnel-shaped opening into the upper part of the canal from the abdominal cavity. This peritoneal depression, or pocket over the site of the internal ring, is persistent, owing to the slowness with which the neck of the hernial sac is obliterated, and during this time thorough and constant protection must be afforded by mechanical support. That the neck of an old hernial sac may become obliterated is shown by the fact that hydrocele not uncommonly occurs within the sac itself, and that even though it become larger than the hernial protrusion which originally occupied it, the fluid cannot be returned to the abdominal cavity.

This has occurred twice in my own practice following the cure of the hernia by injection, and I have seen another case following the cure of a femoral hernia. Oblique inguinal hernia of recent date, where few pathological changes have taken place, is, of course, the most readily cured by this method.

Those children who do not obtain a cure by means of a truss during the first year of treatment, are frequently cured without difficulty by the aid of the injection. That many errors have been committed in the performance of this operation I have had abundant evidence. Perhaps the most frequent error has been in making the puncture through the scrotal tissues instead of directly through the integument over the external ring.

There are two reasons why this should not be done, the first of which is that swelling of the scrotum and testicle is quite likely to occur, to the discomfort of the patient and the risk of a successful result. This is probably caused by the fluid following the needle as it is withdrawn, an inflammatory action being much more readily set up in the scrotal tissues than in those about the canal.

Another reason why this method of introducing the instrument should be avoided is, that when the hernial sac is of large size and is adherent, the injection is more likely to be deposited in its interior than outside of it.

I agree with Heaton that this accident will not be attended by any bad results, nor will much, if any, good follow, as the action of the irritant must be upon the canal and not to any extent upon the sac. In invaginating the scrotum the adherent sac is also invaginated upon the finger, and when the puncture is made it is through the fundus of the sac as well as through the scrotal tissues.

Heaton's instructions on this point were clear, and, as a rule, should be followed. He says:[1] "Invaginate the right forefinger in the scrotum and find the external abdominal ring, then with the left forefinger press perpendicularly upon the integument directly over this ring, and use sufficient force to, if possible, press the integument with the finger directly into the ring. The left forefinger being at or in the ring, the spermatic cord and the sac, if in the way, are to be pushed to one side so that nothing may remain between the external pillar of the ring and the finger, except the integument and subjacent superficial fascia."

The instrument is then passed quickly into the canal. With the exception of one or two details I have followed the method described. Respecting the disposition of the cord and sac during the insertion of the needle I differ with Heaton.

As will be remembered, the spermatic cord lies in a groove in that part of Poupart's ligament which forms the external pillar of the ring. In order to enter the canal without injury to the cord, the latter must be lifted out of this groove to give room for the needle. I have found it more convenient to hold the sac and cord to the outer side instead of toward the median line. The beak of the instrument then passes between the finger and the internal pillar of the ring, the sack and cord being between the finger and external pillar.

One other precaution has, I think, saved me considerable trouble. After making the injection, on withdrawing the needle, and some moments after, I make firm pressure over the external ring. The object of this is to prevent the return of the fluid in the track of the needle, and to retain it entirely within the canal, until it becomes distributed upon the tissues inside of the ring.

Other operators have complained of small abscesses following the operation, and as this has never occurred in a single instance in my own practice, I can only attribute it to the precaution named. Some operators in this country and England have thought best to lay the parts open and smear the structures with the Heaton fluid. This seems to me an unnecessary and unadvisable proceeding, adding to the risks of the operation with no advantage gained. If there is any merit in it, let us use it without adding the dangers of a cutting operation. So far, in the hundreds of injections made, no death, nor even serious complication, has been met with; while, according to reliable authorities, a mortality list of seven per cent. or more follows the open operations at present in use.

C. B. Keetley,[1] an eminent English writer, in a valuable paper upon this subject, speaking of the dangers of the cutting operations as at present practised, says: "Many operators of limited experience can still show a virgin record; but I believe that twelve per cent. would not be an exaggerated estimate of the deaths directly due to the open operation for the radical cure of hernia." According to the results of his study of statistics, which appear to have been carefully and impartially made, there is a mortality risk of only 2.5 per cent. to those afflicted by inguinal hernia who rely exclusively upon mechanical support. If the conclusions arrived at be true, then, in subjecting these cases to operation by the open method, we are adding nearly ten per cent. to the mortality risks of the patient. With the oak-bark injections a better record can be shown. No additional risk is incurred, a certain amount of benefit is sure to ensue, and, if the operation is properly done, followed by judicious after-treatment, the percentage of absolute cures will equal those following any operation at present known

In operating I have usually used the hernial syringe bearing my name, a description of which was given in THE MEDICAL RECORD of February 7, 1880. It has since that time been somewhat modified and improved, and has, in the hands of other surgeons as well as my own, proven satisfactory. Its main peculiarity lies in the fact that its cutting point is protected after entering the external ring, and that in the form of a blunt probe it can be carried higher up the canal than one would care to introduce a sharp-pointed instrument.

[1] G. Heaton, M.D.: The Cure of Rupture, p. 40. 1877.

[1] C. B. Keetley, F.R.C.S.: On the Comparative Dangers of leaving a Hernia to the Protection of a Truss and of Attempting its Radical cure; and on the Indication of Preferring one Mode of Operating to another, according to the Case, Brit. Med. Jour., 1885, vol. ii., p. 1054, London.

In this operation I believe that the subsequent management of the case is fully as important as the manner in which the injection is made. The restorative process begins with the introduction of the irritant, but it is by no means completed when the patient is allowed to resume his active duties. The obliteration of the neck of the hernial sac, which remains unreduced in most cases, is a slow process, and until this is at least partially accomplished, to remove the support is only to invite a return of hernia. On the other hand, too strong pressure must be avoided, as tending to weaken the tissues which it is our aim to strengthen.

During the confinement to bed, which should be at least five to seven days, and, as previously stated, a much longer period in extreme cases, I have usually used the bandage described by Heaton. In some cases, however, I have found it inefficient ,and have resorted to a truss which I devised especially for night use. This consists of a metallic spring across the front of the abdomen, to which such pads as may seem best suited to the case are attached. The spring terminates over the front of each hip, and is held in place by a webbing band around the back.

After the operation I apply this truss and put a light bandage over it. This combination is more secure than the bandage alone, and can be worn subsequently instead of a regular truss.

In a paper which I read before the Surgical Section of the Academy of Medicine last March,[1] I called attention to a modification of Heaton's operation which I believe to be important. I refer to the repeated injection of small quantities of the Heaton fluid without confinement to bed. This method is, of course, only adapted to those cases which can be fully controlled by means of the truss, and it is more especially in connection with skilled mechanical treatment of hernia that it will prove valuable. The patient is first supplied with a truss which can at all times be relied upon to retain the hernia. An injection of from five to ten drops of the Heaton fluid is then made in the usual manner, the truss carefully reapplied, and the patient allowed to go about his ordinary duties.

In some cases detention from business on the following day may be best, owing to the soreness of the parts; usually, however, even this is not necessary. One man, whom I cured by five injections, was a laborer in a foundry, and did not lose an hour from his work. These injections should be made at intervals of about two weeks, and at least four or five different times. The quantity of fluid used must be regulated, to quite an extent, by the amount of soreness established upon the first injection. It should not be repeated while any great amount of tenderness remains. I have found many patients willing to submit to this plan of treatment who could not give the necessary time from business to have the regular Heaton operation done, and I have also found the results even better than I had anticipated.

After an experience of seven years in the use of the Heaton operation, during which time I have used it upon over one hundred cases, I feel justified in claiming for it:

First, Freedom from danger.

Second, That about forty-five per cent. of all cases can be cured by it, and in selected cases an average of seventy-five per cent. can be obtained.

Third, That many extreme cases, uncontrollable by means of a truss, can be brought under control by its aid.

Fourth, That it is followed by improvement in almost every instance.

Fifth, That children who have not been cured by mechanical means can in almost every case be cured by this operation.

69 Madison Avenue.

THE THERAPEUTICS OF MINERAL WATERS.[1]

By TITUS MUNSON COAN, M.D.,
NEW YORK.

In what I have to say I shall speak first of the general question of the value of mineral waters as a means of cure, and second, of the ailments that are fitted for treatment at special springs.

1. The allied subjects of mineral waters and of climate, in spite of their close therapeutic association, have received very unequal attention at the hands of the profession in this country. The curative values of climate have been fully and ably discussed. More than one member of this Academy has made important contributions to our knowledge of the subject; the names of Clark, Metcalfe, Barker, Loomis, among others, are inseparably associated with the best that is known and practised in that important branch of medicine that deals with the choice of climates for invalids. The study of this branch of the subject was a study which could not well be avoided; it was, indeed, in a measure forced upon us by the defects of our American climate, which have made it necessary for us to understand other climates than our own. And aside from the strictly therapeutic questions involved, our increasing habit of European travel gives new importance to the question whither to direct both the healthy and the invalid. Those who seek their health abroad are outnumbered by those who seek to preserve it.

The importance of climatic studies, in a word, is well understood among us. For large classes of invalids it cannot be denied that the United States furnish a very inferior article of climate. Whether as tourists or health-seekers, the public has long been in search of better climates than our own; and it is not necessary to make any plea for the study of climato-therapeutics.

But has equal attention been given to the allied subject—one that is of equal importance to the invalid and to the profession—the subject of curative mineral waters? No; a like degree of attention has not been given, though the profession and the public are indebted to more than one among the names that I have mentioned for valuable studies and advice upon this matter. But if we examine our balneological literature as a whole, we shall find it conspicuous, if I may say so, only by its minitude. It is extremely deficient. The foreign literature of the subject is extensive and systematic; but against the learned treatises of Trousseau, Braun, Durand-Fardel, Rotureau, Hellft-Thilenius, Leichtenstein, we shall find but little to put in evidence, in the way of practical manuals at least, except the useful monogram of Dr. George E. Walton on the "Mineral Waters of the United States and Canada." And, to say nothing of systematic treatises, the French and German physicians have produced a multitude of monographs upon special waters—monographs that are often works of great original research and value. The accessible data of the subject are so abundant that the "embarrassment of riches," as the French say, is their chief inconvenience. It will require no long survey of the literature of the spring-cure in all its forms—whether by baths, drinking, or regimen—to show that our French, German, and Italian colleagues have accorded to this important subject, which they call balneo-therapy, a prominence which neither in theory nor in practice has it yet received among us.

But it must be admitted that in therapeutics the amount of attention given to a subject is not always, even in expert or professional hands, the strict measure of its real importance. Is the vogue of mineral springs abroad merely a vogue, a fashion, and nothing more? Which view is the more nearly correct—the foreign view, that mineral springs afford a real and important resource in the treatment of chronic disease, the view that is, I may

[1] An address delivered before the New York Academy of Medicine, December 21, 1866.

say, almost universally held by the profession abroad; or the view which we still hear expressed at home, though less frequently by physicians than by laymen, that mineral springs are greatly overrated as a means of cure?

The claim of mineral waters to a real or serious value in our therapeutic armamentarium is an occasionally contested claim. It is still met, even by some members of the medical profession, with a more or less enlightened scepticism. A healthy scepticism is, indeed, the legitimate mental attitude of the physician; to him, in therapeutics, the injunction to "prove all things" comes with especial meaning and seriousness. Of all men the physician should be the last one to believe too readily. And I confess myself to be by temperament one of the most sceptical as regards the matter of fashionable provings in remedies. For this reason, my own belief in mineral waters, after many doubtings, may perhaps have some interest as a case of genuine conversion. Considerable observation and study of these remedies, at home and abroad, have convinced me of their value in properly chosen cases; so fully, indeed, have they convinced me, that I sometimes incline to think that when St. Paul, after saying "Prove all things," added, "Hold fast that which is good," the apostle might have had certain mineral springs in view.

The common argument against mineral waters is familiar, namely, that the curative effects observed to follow their use are due to change of climate and to regimen, and not to the waters themselves. Even if this were a sufficient explanation, it would not lessen the value of spring treatment as a total effect. No fact of observation is more familiar than that thousands of chronic invalids who go to the springs come away cured. Such a patient may call it the waters or the regimen, but he will say, with the patient at the Pool of Siloam, "One thing I know—that whereas I was blind, now I see." The change of outward environment is certainly an important part of the cure, but it is by no means all. A large proportion of the waters used are actively medicinal. The arsenical waters of La Bourboule, for instance, the bitter Hunyadi Janos, some of the stronger of the Saratoga waters, can only be taken with advantage, or indeed with safety, in small doses. Nearly all of the calcic waters and many of the saline are most imperatively purgative. For better or for worse, they are at least active medicines. It is they primarily that produce the physiologic effects that are noted; it is idle to ascribe laxative results to landscapes, or a liver-cure to a new social environment. A changed dietary may, indeed, have its effect, but it is not the sound of cowbells or the sight of glaciers that produce fluid stools. It is the waters, not the skies, that make the treatment in places like La Bourboule, Carlsbad, Vichy, Royat. Travel and change do much, but not all; *Cœlum, non cœcum, mutant, qui trans mare currunt.* The physiological effects—tonic, alterative, reconstituant, or depressing—are facts which neither physician nor patient will question. The various waters which produce them make up the therapeutic gamut from which the physician seeks to combine the harmony of health.

The range of the effects of mineral waters is a wide one. Referring them as medicines to the excellent classification of our colleague, Dr. Wm. H. Thompson, they come, for the most part, under the class of Disease-medicines, or medicines for diseases or morbid conditions, rather than Symptom-medicines. Under the former general class they occur either in the division of Restorative medicines, containing the ingredients of the system or substances analogous to those ingredients, as many of the alkaline, iron, and other tonic waters; or in the division of Specifics, or disease-medicines unnatural to the system, as the so-called "alterative" mineral waters, of which the arsenical waters of La Bourboule are a type. But some of the most important of the mineral waters are found under the second main class—that of Symptom-medicines—and under the second division of that class—that of Eliminative or Glandular medicines. To this class belong most of the many cathartic and diuretic waters. Under each of these classes there is no doubt that very many excellent waters are available for the cure of disease, especially among the alkaline waters, which contain the elements of the serum of the blood, and some of these waters in the accurate proportions given in the blood.

It is true that the vogue of remedies is not in itself a proof of their value, if we take into account only a comparatively brief experience. But in this case there can be small question of mere vogue or fashion; it is a question of over two thousand years of use and frequentation. Many of the French, German, Italian, and Spanish springs that are the most highly prized to-day were frequented and highly prized by the Romans, and some of them by the native tribes that preceded the Romans, as in the case of some of the springs of Auvergne. During that great calamity to civilization, the downfall of the Roman Empire, the mineral springs of Europe were, for the most part, forgotten, and their splendid establishments fell into ruin. Throughout Southern and Western Europe their remains are still to be found in many places; and in some spots, as at Plombières, they will show you what they claim to be the plumbing of the fifth century, constructed, I dare say, upon principles now quite antiquated. But from the time of Hippocrates to our own, no other class of remedies has better held the confidence of physicians and of the public than those which we are now considering. Fashion has undoubtedly played her part in the case of individual springs; some that were once famous are now abandoned, or nearly so—a thing that has happened more than once in England, where, more than in other European countries, the aristocracy sets the fashion. But this fate has very seldom befallen springs of really positive medicinal quality. The great springs of the Roman time are great springs to-day, and a multitude of newer waters have been added to the long list of "cures," as the Germans, with cheerful and not ill-founded confidence, are in the habit of calling mineral springs in general. It will be enough, perhaps, to remark that in France alone the number of separate springs that have establishments is about two hundred, France possessing more known springs and more establishments than any other country, though unfortunately they are less known outside of France than they should be. In Germany the number of springs and of establishments is not very far behind. And at all the principal resorts, both at home and abroad, the number of patients steadily increases from year to year.

2. And now let us ask, to what classes of disease is treatment by mineral waters adapted? Whether at home or, preferably, at the spring itself, with the adjuvant influences of changed climate, regimen, scenery, and surroundings generally, who are the sufferers that may expect relief or cure from mineral waters?

3. The converse question, and a very distinct one, is equally important: To what particular spring, in the particular case, shall the physician send his patient?

Experience gives full answers to each of these inquiries. To one of them the answer will be anticipated. Treatment by mineral waters is adapted to chronic diseases only; but to all, or nearly all, such diseases as have any quality of curability about them. Ailments that have proved reluctant to other forms of treatment, however long their standing, often find relief or cure at the rightly chosen spring.

And what are the chronic diseases that are not incurable? The list is a very long one, too long to be recited here. From it we must exclude, of course, malignant diseases, and in their advanced stages phthisis, Bright's disease, and diabetes. Much the greater part of the chronic diseases that remain are adapted to spring treatment; this, in a word, is suitable to nearly all chronic invalids who belong to the curable class—a class which our friends, the surgeons, sometimes claim as forming the distinctive and appointed province of surgical as distin-

guished from medical art. Let me recall here a reminiscence of James Syme, the famous Scotch surgeon, at whose clinic, at the royal infirmary in Edinburgh, I found myself, fresh from hospital and naval service, one morning a good many years ago. After the last patient had been dismissed, and I had been duly introduced to Mr. Syme, he said, "You have very learned medical men in New York, and skilful surgeons. Pray tell me how you discriminate medical cases from surgical cases over there?" To this question I gave the best answer I could, the staff assistants listening with curious interest to the stranger. "Very good," cried Mr. Syme, when I had done, "very good indeed; but now let me tell you how we distinguish medical and surgical cases here in Edinburgh. Any case that admits of either relief or cure we call a surgical case. All cases that admit neither of relief nor cure we call medical cases." This was a surgeon's definition. If we should adopt Syme's distinction, we should send nothing but surgical cases to Saratoga, Carlsbad, Vichy, Royat, and Ems. But, in point of fact, I have sent more medical than surgical cases to springs at home and abroad.

There are enough cases that are intractable to home treatment, and that are still not incurable, to make it well worth our while to classify them, if not to enumerate them at length. In the table of contents that is prefixed to his learned treatise on balneotherapy, Helfft gives four closely printed pages of the names of ailments that he describes as suitable to treatment by mineral waters. The simpler their classification the better.

My own classification is made entirely for working convenience. It is as follows: I divide the diseases that are amenable to treatment at mineral springs into—1, diseases of the digestive organs; 2, diseases of the nervous system; 3, diseases of the respiratory tract; 4, diseases of the uterine system; 5, diseases of the urinary system; 6, skin diseases; 7, general diseases or diatheses. Under each of these heads I will indicate (*a*) the main ailments which are amenable to the mineral-water treatment, and (*b*) some of the particular springs at which the ailments in question should be treated.

1. Diseases of the digestive organs. This is much the most numerous class of all the diseases that we find at the springs. Indeed, it is probably quite as numerous as all the rest put together. At Saratoga, at Vichy, at Carlsbad, at all the more fashionable spas of both hemispheres, the majority of the patients are sufferers from some form or other of digestive derangement, and these derangements are usually, in the case of the European patient, the result of overeating and overdrinking; and often, if not usually, of hasty as well as of excessive eating in the case of the American. The specific diseases chiefly treated are dyspepsias, catarrh of the stomach and of the intestinal canal, enlarged liver, fatty liver, gall-stones, ulcer of the stomach, and enlargement of the spleen.

For the treatment of this wide range of complaints, a great number of mineral springs present themselves; and among them choice must be made—1, according to the type of the disease; 2, according to the need of the individual case. For acid dyspepsias the typical waters are Vichy, Carlsbad, Ems; and at home, those of Saratoga, the Capon, and the Buffalo Lithia Springs. For atonic dyspepsias the patient must preferably employ one of the saline waters, as Salins, or Salins-Moutiers, in France, Kissingen in Germany, the Hathorn or Ballston Springs at home. Stubborn dyspepsias of whatever type that have gone on into gastric catarrh, properly so called, with inveterate gastric lesions, require the glauber-salt waters, as Carlsbad and its congeners—Marienbad, and Tarasp in the Grisons.

2. Next come diseases of the nervous system, as chorea, epilepsy, hypochondria, hysteria, chronic myelitis, paralysis in some but not in very many cases, and many cases of so-called general nervousness and neuralgias. Hypochondriac and hysteric patients often receive the greatest benefit at a well-chosen spring, the entire change of environment, spiritual and physical, seldom failing to produce prompt and often radical benefit.

The number of the springs that are adapted to the treatment of nervous diseases is even more numerous than that of the varieties of the diseases themselves. Royat, Néris, Bagnères de Bigorre, Guillon-les-Bains, in France; Teplitz, in Bohemia; Wildbad and Schlangenbad, in Germany—these are waters that will certainly minister, at least, to a mind diseased, when they do not absolutely heal it. Shakespeare knew nothing, so we must presume, of mineral waters, for he makes no reference to them in the whole range of his writings—the writings that reflect so much of the knowledge of his time. But Shakespeare, happily for us, was the healthiest of men and of poets. Had he known gastric catarrh, for instance, he would surely have gone to some neighboring mineral spring—not to Leamington, the nearest spring, for Leamington was not known until the end of the eighteenth century; but Buxton and Bath, to which latter place Queen Elizabeth resorted, were already popular; and if Shakespeare had gone to either spring, he would have written the "Dyspeptic's Complaint," instead of the "Sonnets."

3. Diseases of the respiratory tract, especially chronic laryngitis, bronchial asthma, the earlier stages of phthisis, and that ill-omened distemper post-nasal catarrh—the national disease, and one which has brought reproach upon our national manners—come next in order. Let me say, in passing, that while the world has reproached us with expectoration, its blame as against the national manners is quite unjust. The blame lies with our climate and our dirty city streets. These cause catarrh, in greater or less degree, in probably forty per cent. of individuals who are over twenty-five years old. It is in no mere unscrupulousness of expectoration, as foreigners assume, that the real cause of this evil exists. For post-nasal catarrh the patient should go to Aix or Mont-Dore; but energetic local treatment in addition is sometimes needed.

The treatment of laryngeal and of pharyngeal troubles has been much attended to of late years at the Continental spas. Aix, Ems, Royat, and the leading springs of Auvergne and of the Pyrenees are the chief places of resort. In Auvergne, and also in the Vosges, I found in the summer of 1885 extremely complete and elaborate appliances in use for the local exhibition of mineral waters, by spraying or pulverization, in the treatment of various diseases of the respiratory passages—a form of treatment that has been introduced of late at some of our home springs, though in but few as yet. There is no doubt of the efficacy of this mode of treatment in many cases. For laryngitis, or "clergyman's sore throat," I choose among the sulphur waters rich in sodium, or the alkaline, with chloride of sodium. Eaux Bonnes, Ems, Obersalzbrunnen, Neuenahr, Selters, Sharon Springs are typical and excellent waters of these kinds.

For beginning phthisis in nervous and sanguine temperaments, treatment at Mont-Dore, at Ems, at Salzbrunnen, at our own Red Sulphur Springs in Virginia, is to be preferred. In the phthisis of scrofulous temperaments the springs of La Bourboule are especially useful. For torpid scrofula, Salins, Kreuznach, Ischl, Kosen, Bourbonne-les-Bains, Rockbridge Alum, Greenbrier Springs are indicated; and any of our stronger saline waters at home. For irritable or "erethic" scrofula, La Bourboule, St. Nectaire, and other springs of Auvergne.

4. Diseases of the uterine system. Among these may be named uterine catarrh, amenorrhœa, dysmenorrhœa, and metritis; these are all suitable for treatment at mineral springs, and they are all relieved or cured, and sometimes with them the resulting sterility at a properly chosen station. In Austria, the springs of Franzensbad are famous for the cure of this class of ailments; in France, Bourbon-Lancy, Plombières; in Germany, Pyrmont, Elster, Schlangenbad, and the Bubenquelle at Ems; of our own waters, Capon Springs and the Buffalo

Lithia No. 2, among other tonic waters, are excellent. For cases of obstinate morning-sickness the waters of the Irondale Springs have been prescribed with good results.

5. Diseases of the urinary system form an important branch of the treatment by mineral waters. Chronic catarrh and rheumatic affections of the bladder, urinary calculus, and sometimes Bright's disease in its early stages, are amenable to this treatment. In uric-acid or red gravel, the most frequent form, and in oxalic gravel, as Trousseau has pointed out, the alkaline waters should be chosen: Vichy, Carlsbad, Ems, Neuenahr, Buffalo Lithia, Capon Springs, Gettysburg "Catalysine." For alkaline gravel I prescribe the calcic waters. Clysmic is one of the best, and it is also a very pleasant table-water.

6. For skin diseases the sulphur and arsenical springs offer a vast field of choice, according to the character of the case. But here we come upon debatable ground; some authorities, like Braun and Hebra, among others, contending that skin diseases do not yield to the treatment by mineral waters. But therapeutic art is nothing if not practical, and experience shows us that a great number of patients come every season to the springs with chronic dartrous diseases who go away from the springs relieved or cured. If they are not cured by the springs, they are certainly cured at the springs, and the exact nature of the distinction is one in which the patient at least will not take much interest.

7. General diseases or diatheses, as chronic gout or rheumatism, scrofula, anæmia, obesity, are often cured at a well-chosen spring.

The anæmia of the scrofulous diathesis is to be treated at a saline water, as at Salins, or Salins-Mouthier in the east of France, or at the Hathorn Spring of Saratoga. The anæmia of exhaustion requires, on the contrary, the effect of an iron water; it will best be treated at such a place as Bussang in the Vosges—a spot so beautiful and quiet as almost to make one desire a sufficient degree of anæmia for himself and his friends as to justify one in taking up his abode for a time among those enchanting hills.

For constitutional anæmia the reconstructive and tonic waters are needed, in conjunction with such diet as will restore the lacking elements of the blood. Beef-peptonoids for the anæmia of dyspepsia; gluten bread and whole-wheat bread for that of diabetes; cod-liver oil and milk for that of the phthisical diathesis, are indicated. The springs of Auvergne, and of Salins, Luxeuil, and Bussang, in France; Franzensbad, in Austria, and the Columbian Spring at Saratoga will bring relief or cure when used with these adjuvants. When chlorosis accompanies constitutional anæmia, the contrasted influences of Alpine resorts and sea-bathing are alike useful.

Such, briefly, are the main classes of disease which we may rationally hope to relieve, and sometimes to cure, at the rightly chosen spring. It is not possible, in the brief time at my disposal, to indicate much more than the general types of ailments, the general classes of springs at which a cure may be sought. Still less can I enlarge in this place upon another order of conditions which, as I have said already, and wish to say once more, are scarcely less important to the cure than the right choice of the mineral waters themselves. I mean the external or the extra-medicinal conditions of the place, as hamlet, village, town, or city; the nationality and the social condition of the people whom the visitor will meet; the advantages of scenery and attractive environs; the *personnel* of the guests and of the physicians; and, not least of all, the kind of hotels, boarding-houses, and furnished rooms which he will find. Most of these conditions, though I have called them extra-medicinal, are very directly related to the cure of the invalid; and most of them can only be well understood by personal acquaintance with the places in question. I do not underrate the purely medicinal side of the question; it is all-important; and yet no part of my own studies in mineral waters has been better repaid than the visits that I have made to many of the leading springs. In a word, it is not enough to say to the patient, This is a good mineral water; it is not enough, even, to say, This is a water that is suited to your case. The physician must be able to say also: Not only the waters, but also the climate, the country, the people, the local treatment, the hotels and boarding-houses, the ways of living, the place as an entirety, are suited to your particular case. When the physician can know these things the cure of his patient is not far away. And he can know all of these things only by personal inspection. All of these collateral points should be, as far as possible, familiar to the consulting physician on whom the grave responsibility devolves of sending the patient far away from home, and who clearly recognizes that the waters are by no means all in themselves; that these complicated and delicate remedies depend for their success, in no small degree, upon the right selection of the conditions under which they are used.

To recapitulate: Three different things must be clearly known, in respect to each patient, before he is sent to a mineral spring. What are these three things? They are, first, the patient's disease; second, the mineral water that is medicinally adapted to the treatment of that disease; and, third, the hygienic, social, personal, and living or commissariat conditions of the place to which the patient is going.

I have one remark to add. I think that treatment by mineral waters, both at home and abroad, is destined to increase greatly within a few years from now; and I believe that that increase is to take on a sort of reciprocity or international character as our own excellent native waters become better known abroad. They will become better known as our establishments are developed and made more attractive; when that is done—when we come to have more of such admirably appointed establishments as the Sanitarium at Dansville, N. Y., for instance—I look for European invalids to frequent our waters as we have learned to frequent those on the other side of the Atlantic; with the illustration of Saratoga in view, it is not necessary to say how attractive an American watering-place may be made. The only lack at Saratoga is the willingness to submit to scientific treatment. A number of other domestic springs, especially in the Eastern States and in Virginia, have received all of the outward development and perfecting that are required to make them charming places of resort. But for the greater part of our springs much remains to be done. Much remains to be done not only in the way of outward perfecting, in the construction of hotels and establishments, but in equipping them as true places of healing, and in making them regarded as a serious means of cure. They are so regarded abroad, and with reason, as I have tried to show. They are less so regarded with us, and more regarded as places of recreation; and this is an unfortunate, because an insufficient, view of their values. Mineral springs are most potent, if delicate, remedies; and the danger is that their real therapeutic value may be overlooked by the public if it is not sufficiently insisted upon by the profession, and that they may lose the vogue that they deserve—a thing that has already happened to at least one very deserving spring in this part of this State.

The fitting development of our excellent but still undeveloped springs presents, in my opinion, a field both to professional and to business enterprise that is second to none. Virginia, for instance, is but one among several States in which there are excellent springs that have in past times been popular, and may be made popular again, but which through mismanagement of one kind or another have now lost their vogue; and this decline, I would say in passing, has generally been due in part to a very easily avoidable cause, which I have not yet mentioned. It has not been due to any demerit, real or fancied, in the waters themselves; it has not been due to insuffi-

cient skill in the attending physicians, though, as I have said, we do not as a community give such high medicinal rank to spring treatment as it undoubtedly deserves. No; it is a more trivial cause than either of these, and yet one that is quite sufficient to disperse the stoutest-hearted colony of settlers, especially if those sojourners be dyspeptics—and that cause is bad cooking. A poor *cuisine* will put to flight the most courageous invalid. A good *cuisine* must go with a good spring, or success will not attend the management. One great secret of the popularity of the French springs is the attention given to this important point. Even at the newest establishments, as at Martigny and Bussang, an exquisitely appointed *cuisine* has appeared from the first, and dining-saloons have risen from the ground like the dinner-tables of Beckford or of the late King Ludwig of Bavaria. These things, in connection with a competent medical direction, and a serious medical and hygienic treatment, have not yet reached that satisfactory development at our springs that they have found in the older countries of Europe. But this development will come in time, and foreigners will then seek American mineral springs for the same reason that we shall long continue to seek the springs of Europe, for the conjoined and manifold benefits of a completely changed environment.

The domestic use of mineral waters is an important subject for the many persons who cannot leave their homes for treatment at the springs. I have discussed it in a paper to appear elsewhere, and I will not here enter upon it at length. It is enough to say that such domestic use is often very helpful to the invalid. The home use of mineral waters will seldom, indeed, adequately replace the trip to a mineral spring; the reasons for this I have already pointed out, in the different circumstances of life at a spa, in the relief from home anxieties, and in the almost invariably stricter medical supervision abroad than at home. All these postulates of spring life must make it the preferable means of treatment. Yet for many the home use of a rightly prescribed water is a valuable cure. And not only are the natural mineral waters valuable when taken at home, but some of the artificial waters also, as Schultz's and the various hygeia waters, which are the best among many. All these offer an undoubted resource.

One caution, finally, is to be borne in mind by the patient. Mineral waters, though delicate, are powerful remedies. They are not to be taken at the patient's choice or whim any more than other medicaments. That they are often self-prescribed is a main cause of their slow recognition by our public. The American tourist likes to prescribe for himself; he likes to choose his own spring when he will and where he will; he insists on eating, drinking, exercising, amusing himself, or abstaining from all of these things, as he alone may elect. I need hardly say that the latter state of that invalid is apt to be sevenfold worse than the first.

It is the physician's duty to check this undue liberty. Rightly chosen, rightly prescribed, and under the right conditions, the mineral springs of our own country, intrinsically as good as any of those of Europe, are among our most valuable remedies in chronic cases. After other remedies have failed they will often bring relief or cure. Let us claim for them and restore to them their true value.

THE LATE PROFESSOR POST.—Dr. S. Haynes writes that in the winter of 1852–53 he witnessed the reduction of a dislocation of the cervical vertebræ by Dr. A. C. Post. The man was placed on the operating-table, and by means of extension and counter-extension, with a little manipulation, the dislocation was readily reduced. He adds that Dr. Post was known as a stanch temperance advocate, and says that it was currently reported among the students at that time that he had voted against the granting of diplomas to fifty students at the previous session on account of their intemperance.

Clinical Department.

REMOVAL OF THE UTERINE APPENDAGES.

DR. WM. B. BLACKSTONE, of Hebron, Ind., reports the following cases: "1. Mrs. E. J. W——, aged twenty-nine, and married nine years, has had two children and one miscarriage, the latter occurring in September, 1882. Since that time she has had constant backache, painful micturition, headache, loss of appetite, constipation, and a peculiar throbbing, boring, burning pain in the right iliac region, and on the right side of the uterus a constant, dull, heavy ache. The menstrual periods occur regularly, but are attended with a profuse flow, great pain, and considerable elevation of temperature. They last from six to eleven days, and during the past year there has been a yellowish discharge, of an offensive odor, from the vagina. The uterus is congested, retroflexed, and slightly enlarged, any attempt at replacement causing intense pain. The right ovary is enlarged, exquisitely sensitive, and prolapsed into the retro-uterine cul-de-sac. After six months of persevering treatment, without relief, an operation was proposed—the dangers and the probable benefit being fully explained to the patient—and was consented to. The operation was performed on May 19, 1886, both tubes and ovaries being removed without much difficulty. There were no adhesions of any consequence on the left side, but on the right side there were broad and firm, but non-vascular, bands connecting the tube with the uterus and ovary. The cavity was thoroughly cleansed with warm water, the wound closed with silver and catgut sutures, and the usual dressings applied. The patient made an excellent recovery. The inner portion of each ovary was occupied by a large cyst containing a dark fluid, and the outer portion was marked by several nodular projections, consisting of dense fibrous tissue. Both tubes were tortuous, enormously distended, and filled with a greenish fluid, seen, under the microscope, to contain pus-cells.

"2. Mrs. L. McA——, aged thirty-seven, has had nine children and three miscarriages. She has constant backache, a dragging sensation in the pelvis and thighs, and a heavy, boring pain in the iliac region on either side of the uterus. Before each menstrual period there is a discharge of pus from the vagina, after which there is some alleviation of the symptoms. The periods occur every three weeks, and each one is ushered in with a chill, followed by a fever of several days' duration. The flow continues about ten days and is very copious. There is a bilateral laceration of the cervix extending back to the vaginal vault. The endometrium is studded with a fungous growth. The uterus is large, sensitive, and bound by strong adhesions posteriorly. The appendages on either side are thickened and sensitive. The patient is anæmic, and has been bed-ridden for the past eight months. The operation was performed on June 29, 1886. Before the administration of the anæsthetic, cocaine hydrochlorate was given by the mouth to prevent nausea. The operation consumed one hour and thirty minutes, being prolonged by reason of the extensive adhesions which bound down the ovaries and tubes, making their removal extremely tedious and difficult. The omentum was adherent to the anterior surface of the uterus, but the two were easily separated. The uterus was, however, firmly bound down by other adhesions and could not be raised. The left tube and ovary were first removed. The right tube and ovary were buried in a mass of adhesions. After these were broken up, the organs were raised and ligated off, but the stump was so rotten that the ligatures cut through, and each artery had to be caught and tied separately. The wound was closed by silver and catgut sutures. In three weeks after the operation the patient was sitting up. The right ovary was enlarged and its surface was marked

with cicatrices and numerous small cysts. On section its interior was found to consist of one large cyst filled with a thick, gummy, translucent material. The tube was large, folded on itself, adherent everywhere to the ovary, and contained pus. The left ovary was small, but was found to contain a cyst filled with the same material as the right. The tube was large, distorted, and bound down to the ovary. Both tubes were soft and friable. It is now six months after the operations, and both women are rugged, robust, and in perfect health." Dr. Blackstone concludes: "That the operation is a justifiable one in all intractable cases of this kind there is, to my mind, no doubt. And in the future, I am inclined to think, it will be performed oftener than it now is; for in it is offered the only means of cure to a very large class of unfortunate women."

Progress of Medical Science.

The Surgical Relations of the Ileo-cæcal Region.—Under this title Dr. J. McF. Gaston, of Atlanta, Ga. (*The Journal of the American Medical Association*, October 9, 1886), considers the frequent derangements of the ileo-cæcal region. As a result of his investigations he formulates the following conclusions: "First, certain modifications are corrected spontaneously, or by the process of resolution under treatment. Second, in the earlier stage of ileo-cæcal disorder, medicinal or mechanical measures are advantageous. Third, extra-peritoneal punctures and incisions are beneficial in cæcal inflammation, with or without fæcal abscess. Fourth, disorders involving the peritoneum, when not promptly relieved by general treatment, warrant exploratory opening of the abdomen. Fifth, impediments of the intestinal canal, or morbid accumulations in the abdominal cavity, accompanied by meteorism, call for immediate surgical interference, with laparotomy. Sixth, in case of simple stenosis or malignant growths involving the ileo-cæcal connections, ileo-colostomy is indicated. Seventh, gangrenous portions of the intestinal canal necessitate resection, and either direct restoration by suturing the ends or the formation temporarily of an artificial anus. Eighth, operative measures in ileo-cæcal derangements should not be delayed until the physical powers have become prostrated, but resorted to while there is capacity for reaction of the vital forces.

Abdominal Pregnancy Terminating by Ulceration into the Rectum—Recovery.—Dr. Browne reports this remarkable case in *The Lancet*, October 2, 1886: "E. J——, aged forty. Has had ten children, the youngest being five years old. Has not had any miscarriages, and gives no history of previous disorders in the organs of gestation. She had last menstruated in November, 1884 (seventeen months previously). She believes herself to have been in her usual good health, and does not remember to have had any fright about that time. In the course of a month or so she began to suffer from metrorrhagia, which continued, and led her to seek advice. On examination, a tumor was found upon the left side of the abdomen. From its position and feeling it was diagnosed as ovarian, and it was also suggested to the patient that she was pregnant. The metrorrhagia continued, more or less, until in September, 1885, or at what would be about the full period of pregnancy, a pseudo-labor took place, and an effort at lactation appeared in the breasts. About this time the patient began to notice that the tumor seemed smaller. She complained of loss of appetite, general ill-health, and pain and irregularity in the action of the bowels. This state of things continued until April last, or seven months after the pseudo-labor, when she was taken with violent forcing pains in the body and lower bowel, and offensive diarrhœa, in the course of which some fœtal bones were passed. Examination of the rectum disclosed the presence of the remainder of the fœtus. A hand was introduced into the bowel, the fœtal head crushed as far as possible with the fingers, and its fragments and other bones removed. The diarrhœa, and the occasional passage of a remaining bone, continued for a few days, gradually became less offensive, and then ceased. Within a fortnight the patient was able to leave her bed, and has since made an uninterrupted recovery. From the frontal bones removed entire, each measuring an inch and a half by an inch and three-fourths, and from the other cranial bones fitted together, the bi-parietal diameter was computed to be three inches. All the bones had the normal amount of ossification of a full-time fœtus. Points of interest in this case are: 1. The difficulty of diagnosis, though, looking back now, nothing can be clearer than the sequence of events. 2. The maturity and perfect formation at which the fœtus arrived. 3. The means taken by nature to remedy her error, and which resulted in perfect recovery."

Cold Applications to the Præcordia in Fever.—Dr. Grigorovih has studied the effects produced by applying cold over the region of the heart in typhoid fever. His observations were made on uncomplicated cases of the disease. Respiration, at first, became somewhat quickened, and was rendered irregular by reflex action; subsequently it became slower. At the end of the application of the ice, and the next morning, it was deeper and more regular, but somewhat slower than before the ice was applied.

The general conclusions regarding the effect of applying cold to the region of the heart are as follows (*The Therapeutic Gazette*, ~~October 15, 1886~~):

1. The cold undoubtedly reaches the heart itself, and thus produces an effect upon its action.

2. This effect is particularly noticeable when the cardiac beats are increased in frequency in consequence of a high temperature quickly attained, and where a certain degree of sensitiveness to a high temperature exists.

3. The effect of cold is not marked at the end of a prolonged attack of fever, pathological changes having by that time probably become established in the cardiac muscle.

4. The local application of cold is only capable of protecting the heart-muscle from the effects of a high temperature when it is applied assiduously from the commencement of the disease.

5. Under its influence the action of the heart improves, the number of beats diminishes, while their force and amplitude increase.

6. Cold applied to the region of the heart diminishes the gravity of the typhoid condition and favorably influences the respiration.

7. With regard to the effect of cold applied to the region of the heart on the course of the general temperature, the author cannot at present express a decided opinion, as he did not investigate the question: but in the results which he obtained indications may be found of the possibility of its causing some diminution of the temperature.

Why do not all Myopes Squint Outward?—Dr. F. Stilling answers this question as follows: 1. Some myopes squint inward because their position of rest is convergence, and there may be insufficiency of the external recti besides. 2. The position of rest of many myopes is convergence. If this be only slight, only relative divergent squint can possibly develop. The same holds good for parallelism as position of rest. 3. Even if all circumstances are favorable for outward squint, it will not develop if the individual cannot learn to relax one internal rectus muscle in order to give the eyeball a chance to assume its position of rest. 4. The majority of myopes do not squint because they have acquired the faculty of shifting the range of relative accommodation in the interest of binocular fixation so that the synergistic efforts of accommodation are reduced to a minimum. —*American Lancet.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 8, 1887.

A QUESTION OF COMPENSATION FOR EXPERT TESTIMONY.

WE have to thank several correspondents for calling our attention to what we cannot but regard as a legal outrage, which has been perpetrated against a prominent physician living in Southwestern Ohio. The facts of the case are as follows: Dr. F. H. Darby, President of the Miami Valley Medical Association, living in Morrow, a town not far from Cincinnati, was summoned to Lebanon as a witness in a wife-murder trial. Being put upon the stand, he made the statement that he would testify to all matters of facts within his knowledge, but would refuse to give expert testimony unless he were assured a certain fee. The judge informed him that the fee could not be allowed, and that, according to a recent decision of the Supreme Court of one of the States, physicians could be compelled to give expert testimony without extra compensation. The examination then went on, the witness answering readily all questions put to him concerning facts within his own knowledge, until the prosecuting attorney asked him to "state whether, in wounds like this, there would be immediate gaping, or would the lips of the wound for a time remain in contact or nearly so?" This question Dr. Darby refused to answer unless he were guaranteed a fee of $25 for expert testimony; and, as he persisted in his refusal, he was committed to jail to be confined until he was ready to purge himself of the contempt of court. The witness spent two nights in jail, still refusing to recede from the position he had taken; and whether he has even yet been liberated we are unable to say. He is determined, however, not to yield, and will carry the case up to the Supreme Court, if necessary, in order to see whether justice can be guilty of such injustice.

We do not know what State it is in which the Supreme Court has handed down the decision that professional men may be compelled to give expert testimony, but we do know that other decisions have been made which affirm directly the opposite. Tidy says, in his "Legal Medicine," that no witness can be compelled to give his *opinions* in the witness-box, and no one is bound to accept a subpœna merely to state opinions. The witness that can speak to any actual fact connected with a case must attend the trial if he be required to do so, but the expert, however wide his experience, cannot be forced to give the court the value of his general or special knowledge. This, of course, refers only to English law, and the law in this country is not necessarily the same. Mr. Henry A. Riley, a well-known writer on subjects pertaining to legal medicine, is the author of an article on the Law of Expert Evidence in the "Reference Handbook of the Medical Sciences." In this article he says that, while an ordinary witness may be compelled to testify to facts within his knowledge which may be important to the just decision of the case, experts are in a very different position. "It has been fully settled," he says, "that expert witnesses are not obliged to give testimony against their will in cases where they are subpœnaed. They would probably be guilty of contempt of court if they did not obey the subpœna, but they cannot be compelled to testify as to their opinions upon assumed facts if they do not desire to. The payment of a proper fee may be made a condition precedent to testifying. If, however, an expert witness begins to give testimony without raising the point of a failure to compensate him, he cannot stop of his own motion. He is obliged to continue his testimony until his examination is concluded."

We all know that law and equity are not synonymous terms, but it is certainly not justice to compel a man to give for nothing what he has spent so much time, money, and labor to acquire. If a physician has no right of possession in the special knowledge which has cost him so much to gain, then let us be consistent and divide up all property. Physicians, in common with other good citizens, submit willingly and uncomplainingly to the law, and cheerfully make every sacrifice to perform their duty as witnesses to facts which may be of service in furthering the ends of justice. But there is a limit to even such services. It is the common belief that judges and lawyers are necessary to the proper meting out of justice to evil-doers, but they are not on that account compelled to give their services without remuneration, and there is no justice nor reason in forcing physicians to do so. The State has attorneys whom it pays well to prosecute offenders against its laws, and it should pay the expert witness, if it calls upon him, for the knowledge which he has acquired, and which is as much his own property as are the clothes he has on his back.

We are so accustomed to see the long-suffering members of our profession imposed upon in many ways, and robbed of the fruits of their experience and study, that we have grown somewhat callous. But it is time that we began to assert our rights, and we are glad that Dr. Darby has had the courage to resist the imposition which it was attempted to practise upon him. He deserves the thanks of the profession for the stand that he has taken, and we hope he will be successful in establishing firmly the principle that a physician's knowledge is his own property, which cannot be taken from him without adequate compensation.

LATENT MICROBISM.

WE have had occasion to notice recently in these columns several cases of scarlatina in which there was so little apparent chance of contagion as to suggest the possibility of spontaneous origin. It is true that all diseases of this nature must have had an origin at some

time, but so must all forms of animal and vegetable life have had, at some period in the world's history, a beginning. The experiments of Tyndal and others have, however, shown that spontaneous generation cannot or. at

in the University of Wooster, Cleveland, O., has resigned his position as one of the Secretaries of the Section on Dermatology and Syphilis.

Dr. George Bronson Farnam died at his home, in New Haven, Conn., on December 23d. He was a graduate from the Yale Medical School.

A Doctor's Suicide from Loss of Practice.—Dr.

the body, as in the skin or serous membranes, the connective tissue, etc., which may remain inactive, giving rise to no symptoms whatever for months and years. Finally some disturbing cause, very slight it may be in itself, starts up these latent microbes to renewed activity; they increase rapidly in number, and wander forth from their resting-place to infect the system and set going the morbid processes of disease.

This theory serves well to harmonize the doctrine of contagion with the cases of seeming spontaneity of origin of diseased processes which are met with from time to time. It supposes, of course, that there has been contagion at some time; but it may have been years before the disease makes its appearance, and so the affection seems to be developed spontaneously. But there are two objections, at least, to M. Verneuil's theory. The first is that it assumes that micro-organisms are certainly the cause, and not possibly the accompaniment, of morbid action. The second is that it is founded on pure speculation, and is as yet unsupported by any facts whatever.

A SURE CURE FOR DIPHTHERIA AGAIN.

We feel that perhaps an apology is due our readers for bringing to their notice another of the many methods of treating diphtheria, which are always said to be so successful in the hands of their advocates, but which, for some reason or another, often fail to yield satisfactory results when employed by others. But the therapeutic nihilists must not be allowed to have the ascendency always; and, indeed, some of the methods recommended in recent years, though not specifics, have proved to be very serviceable, and it is not impossible that others may yet be proposed which may be found to be of even greater value. It is, therefore, worth while to consider any new plan of treatment that may be brought forward, or to note any remarkable series of successes which have followed the employment of old methods.

Dr. A. Brondel writes, in the *Bulletin Général de Thérapeutique* of November 15, 1886, concerning the treatment of diphtheria by benzoate of sodium, and asserts that of two hundred consecutive cases he has not lost a single one. He admits the possibility of a mistaken diagnosis in some instances, but even excluding fifty per cent. on this account he still has one hundred cases without a death. His method is as follows: Every hour the patient takes a tablespoonful of a solution of benzoate of sodium, fifteen grains to the ounce, and at the same time one sixth of a grain of sulphide of calcium in syrup or granule. In addition to this, the throat is thoroughly sprayed every half-hour with a ten per cent. solution of benzoate of sodium. This is done religiously at the regular intervals, day and night, but no other local treatment is employed; no attempt is made to dislodge the false membrane, and no pencilling nor painting of the fauces is resorted to. Tonics are given and antipyretics are used when occasion calls for them. The nourishment consists of beef-juice, tender rare meat, milk, etc., but bread and all other articles which may cause irritation of the throat are forbidden. The sick-room is kept filled with steam from a vessel containing carbolic acid, turpentine, and oil of eucalyptus in water.

The employment of benzoate of sodium is not a new method in the treatment of diphtheria; for it has been tried, and is recommended highly by Letzerich, Kien, Ferréol, and others. But this, of course, speaks so much the more strongly in favor of the remedy; and as Dr. Brondel's results were better than those obtained by others using the same drug, it is to be presumed that his method of employing it is the best.

THE ETHICS OF ADVERTISING.

A correspondent from Kansas City informs us that he has read in the daily papers an account of another wonderful operation performed by a member of the staff of one of the teaching institutions in this city. Having seen similar reports of operations by the same individual, he very naturally inquires if it is necessary to belong to that particular body of instructors in order to be allowed to advertise. In the West, he says, they are more refined and cultured in their methods than they are here. Physicians there bring themselves before the public in many ways, it is true, but in a manner more pleasing to their wished-for patrons. They pose as founders of societies of microscopy and art, are prominent in religious circles, and are foremost in all public enterprises and philanthropic schemes of every kind and sort.

This is all very true, and our correspondent is right in claiming that the Western methods are more refined and more in keeping with the requirements of the Code. But he fails to recognize the broad distinction between local and national advertising. The man who works what the wicked call the Sunday-school racket has only a limited sphere of usefulness. He may be called on to treat the clergyman of the parish gratuitously, and through him may get a few fees out of the members of the congregation. But the man who reports his marvellous operations, or who announces himself as delivering a course of lectures, in the papers throughout the country has a more lofty ambition. He desires to relieve the sufferings of his fellow-men everywhere, and not merely those residing within the limits of a narrow section. That our Western brethren are beginning to grasp this idea is evidenced by some startling tales in the papers of a dead person brought to life by a Chicago physician. That is more than the professor, with all his operations, has ever done.

But, as we have said before, the fact that an enterprising reporter writes up an account of an operation for his paper does not necessarily imply that it was done with the consent, or at the request of, the operator. It is only when the offence is flagrant, and is repeated time and again, that it is fair to throw the odium upon the surgeon. A little charity in our criticisms of our professional brethren is never out of place.

THE INDICATIONS FOR THE USE OF ALCOHOL IN ACUTE DISEASES.

It is getting to be a quite well-established canon of medicine that most healthy men are better without alcohol taken in any form or at any time. We are inclined to add that Americans do not bear it so well as Europeans. That it can be dispensed with altogether in medicine, however, is a thing not to be admitted, and medical opinion almost unanimously supports this view. But no doubt alcohol is often used more promiscuously than it should be, especially in hospitals, and the observations and conclusions of Dr. Collie regarding the indications for its use (*The Practitioner*, vol. xxxvii., No. 5) deserve close attention. Dr. Collie admits that alcohol is not required in the mildest cases of fevers, nor in the severe if the patient be taking a sufficiency of food, nor generally in young adults of the well-to-do classes. These are great admissions for Dr. Collie to make; but in opposite circumstances he maintains it is more or less necessary, and we advise our readers to consider his opinions. Briefly, in the chief fevers, to which his authority applies, they are as follows: In *typhus*, alcohol is rarely required for children or adults under thirty; but after this age it is necessary, and often in considerable quantities. It may be dispensed with early in convalescence, as solid food can be taken as soon as the temperature falls. In *scarlet fever*, alcohol is not required, as a rule, at any period of the disease. But in very poor children, in early convalescence, with abscesses or brawny neck, alcohol, in the form of port wine, is indicated. He considers port, say four to eight ounces, good for children of the age of from four to six. For procuring sleep it is better than opium. In enteric fever the chief value of alcohol is during convalescence, where solid food cannot safely be taken for from ten to fourteen days from the return to normal temperatures. Alcohol is contraindicated in cases of hemorrhage unless collapse has resulted. Burgundies and champagne, of well-approved brands, are, he thinks, the best forms.

THE IMMEDIATE CURE OF WHOOPING-COUGH.

Our Scandinavian brethren have been showing considerable activity of late in the line of therapeutics. We reported the results obtained in the treatment of tubercular meningitis by iodoform. Now we find one Dr. Mohn, who claims to have an immediate cure for whooping-cough (*Norsk Magazin for Laegevidenskaben*, November, 1886; *Rev. Internat. des Sc. Méd.*, November, 1886). Dr. Mohn writes that, about six years ago, his three-year-old daughter was attacked with scarlet fever, followed by whooping-cough. At the end of five weeks, when the scarlet fever had run its course, Dr. Mohn fumigated the clothes and apartment with sulphurous acid. The child's attacks of coughing ceased from that day.

Four years later he was called to see a child of three years who was suffering from pertussis to a dangerous degree. Three brothers and sisters were affected also, but not seriously. Dr. Mohn burned his sulphur, and the next day all four patients were cured!

Other cases are cited. An infant of five months, who had had the disease for five weeks; a boy of four years, who had suffered from it for fifteen days, were cured as "by enchantment." Six other cases are reported, all treated with equally brilliant success.

The method is as follows:

Dr. Mohn reported his method to the Medical Society of Christiania, and it was favorably commented upon. It is, at any rate, a new idea, and perhaps a good one, to disinfect a sick-chamber during the course of the infectious disease.

SMALL FEES AND GREAT DOCTORS.

A young physician, practising in this city, writes: "Is there no help for the pitifully small fee which we doctors, in all but the central parts of this city, get? I started in practice here over a year ago, locating in the neighborhood of a large apartment and tenement-house district. I had spent a good many years and a large sum of money on my medical education, having not only passed through a hospital course, but taken special studies abroad. I began practice by charging $2 for visits, but soon found it would not do at all. I was told that Dr. ——, a professor in one of our leading medical schools, only charged $1; so did other old, well-known physicians practising in the neighborhood. It seems to me that long years of experience and study ought to make a physician's advice worth more than it is estimated at by certain active and venerable doctors in this vicinity.

We often are in receipt of complaints of the above kind, and are generally willing to concede that there is some justice in them. It is too often the case that, as physicians grow older they cannot see the wisdom and justice of selling their services at a higher value, thus diminishing, perhaps, the amount of their work, but in reality doing a better kind. We happen to be able to say with positiveness, that the "Professor" alluded to by our correspondent, at an age when he should be resting or consulting, allows himself to be worked to the last point of weariness by the same kind of practice as that with which he began his professional career.

The Emigrants' Hospital.—At a meeting of the Commissioners of Emigration last week, the Ward's Island Committee presented a long report, reviewing the investigation in October into the charges made against the physicians at Ward's Island, regarding the dissection of bodies and appropriation of specimens, and exonerated the physicians. The committee, however, thought the interests and efficiency of the medical department would be increased by the appointment of a pathologist whose duty it should be to supervise all autopsies in the department, no autopsies to be performed by persons not members of the medical staff. Dr. John S. Thatcher was appointed.

News of the Week.

Dr. William T. Corlett, Professor of Dermatology in the University of Wooster, Cleveland, O., has resigned his position as one of the Secretaries of the Section on Dermatology and Syphilis.

Dr. George Bronson Farnam died at his home, in New Haven, Conn., on December 23d. He was a graduate from the Yale Medical School.

A Doctor's Suicide from Loss of Practice.—Dr. Henry Andrews, a graduate of Long Island College Hospital, and a resident of Brooklyn, shot and killed himself, on December 25th. He was an unmarried man about forty-seven years old. It is stated that despondency from failure to secure practice was a cause of the suicide.

The American Rhinological Association would be pleased to have authors send any monographs, papers, or books, treating of any disease pertaining to the nose, throat, or ears, to the librarian, Dr. N. R. Gordon, Springfield, Ill. The acknowledgment will be made by the Association.

The Suicide of Professor Kolomnine. — The *Semaine Médicale* gives some particulars of the accident which led to the suicide of Professor Kolomnine. The professor had decided to perform an operation for the removal of tubercle from the rectum of a female patient, and inquired of his colleague, M. Louschinsky, what dose of cocaine he might administer. The answer was that the maximum was two grains. Upon consulting special treatises, however, M. Kolomnine found that thirty cases of anæsthesia were recorded in which the quantity given had varied between six and ninety-six grains. In a similar operation to that he proposed to perform, a French surgeon had given forty-eight grains. In consequence of these references it was decided to employ twenty-four grains, which were introduced into the rectum by instalments. About half an hour after the operation the first symptoms of poisoning appeared, and notwithstanding the administration of nitrite of amyl, hypodermatic injections of ether, oxygen and artificial respiration, etc., the patient succumbed.

The Centennial of the College of Physicians of Philadelphia.—The commemorative exercises of the one hundredth anniversary of the College of Physicians were begun, Monday evening last, with an address by the President, Dr. S. Weir Mitchell, in Association Hall, in the presence of many of the prominent physicians of the city. Dr. Mitchell, in opening his address, spoke of the institution as the oldest medical society, not a State organization, in America. He gave an account of those who formed the college in the latter part of 1786, and who met first, January 2, 1887, speaking of the life and character of Benjamin Rush, John Redman, Samuel Powell Griffits, and Caspar Wistar, Jr. He reviewed the services rendered by the college and by the fellows in forwarding both professional and public interests. At the close of the address a reception was given in the college building, which was largely attended. A special meeting was held at noon on Tuesday, for conferring the honors of Associate Fellowship. An address was delivered by Professor Alfred Stellé, after which the President conferred the honor of Associate Fellowships upon nine gentlemen. Professor J. M. DaCosta welcomed the new Associate Fellows on behalf of the college. In the evening there was a banquet in the Union League, Dr. S. Weir Mitchell presiding. Over one hundred guests were present. Toasts were responded to by Dr. C. R. Agnew, Dr. T. G. Thomas, Dr. William Pepper, Dr. John Ashhurst, Professor Theophilus Parvir, and Dr. John S. Billings.

A Cablegram states that Drs. Martin and Veil have been chosen as Vice-Presidents of the Gynecological Section of the coming Medical Congress at Washington.

The Hospital Sunday Fund, up to date of writing, had reached the amount of $24,843.19, with prospects of a total exceeding that of previous years. The "banner" church, we believe, is the Broadway Tabernacle, whose collection amounted to $3,420.08.

Northwestern Medical and Surgical Society.—At the annual meeting of the Northwestern Medical and Surgical Society the following officers were elected: President, Dr. A. R. Robinson; Vice-President, Dr. R. C. M. Page; Secretary and Treasurer, Dr. E. S. Peck.

A Dangerous Dose.—Our attention is called to a typographical error in the article on "Arsenic in Skin Diseases," page 14, in which the dose of Fowler's solution is named as one to twenty drachms thrice daily. It should of course be minims.

The Wealth of Families.—The physician is paid well, or otherwise, in accordance with the supply of money in the families among which he practises. There are about eleven million heads of families in this country. Estimating their incomes on the same basis as that of English tax returns, there are only about one hundred thousand families having an annual income reaching $2,000, and only about thirty-five thousand having an income equalling or exceeding $5,000. Out of fifty-five millions of population, forty-five millions earn $15 a week or less.

Guy's Hospital in Need.—Perhaps the worst sign of the agricultural depression in England yet recorded, is that Guy's Hospital is asking the public for subscriptions. "Guy's" has hitherto been a very proud hospital, and has kept house magnificently, in the interest of the suffering poor, on an income of over £41,000 a year, derived from estates in land. But the annual yield of these estates has been diminishing steadily since 1879, until, at the present time of asking, it has come so low as £26,000, with every prospect of further decrease. The total of 650 beds of the old prosperous times has been reduced to 500, and then to 400, and it is believed that the worst has yet to come. At one time, when money meant money, and land was land, Guy's lived in great charitable state on its fortune of £220,000 from Mr. Alderman Guy, and its £180,000 added by Mr. William Hunt, a century later, to make the round £400,000, and never asked the public for a penny.

Light on the Pineal Gland.—Some recent observations of Mr. Baldwin Spencer seem to show that the pineal gland is homological with the vertex eye of lacertilians.

THE MEDICAL ASPECT OF THE COLIN CAMPBELL CASE.—Sheared of its disgusting and prurient details, the Colin Campbell case brings up some very interesting pathological and medico-legal points, particularly with reference to the relation of old chronic gonorrhœa to endometritis and salpingitis. The *Medical Press and Circular* gives the following account of the matter: "Before marriage the husband had been suffering from perineal abscess, the sequel of gonorrhœa contracted some few years previously, for which abscess he had undergone one or two surgical operations—namely, perineal section into the urethra. Marriage took place before the parts were restored to health, but it was previously agreed that separate beds should be occupied for two months or so, in order to permit of recovery. The contention of the wife was that, although he had been operated upon and was not as yet recovered at the time of marriage, yet she had no idea he was suffering from any disorder of the genitals, but had thought it was something of the nature of piles. Communications had been made to her by medical men, but she asserted that this was thus understood by her. However, after some time, permission was given to commence intercourse; but as the husband was again laid up, it had to be discontinued, and further operations became necessary. Intercourse was occasionally resumed, but ultimately the wife's health was affected, and it was found she was suffering from irritation of the vagina and vulva, with uterine leucorrhœa. Local applications were made to the vagina and cervix uteri, but without much benefit. Dr. Braxton Hicks was called in after an attack of very severe pain on one side of the pelvis, who found there a cellulitic effusion; after a few weeks this subsided, but still the uterine catarrh remained, with much irritation of the vagina. As the canal had been well medicated without benefit, the os was dilated. It was evident that the uterine cavity was larger than normal. A silver tube was passed, through which the interior of the uterus was painted over by a brush charged with iodized phenol. This cured the complaint. However, upon overtures being made by the husband for renewal of cohabitation, she begged him to refrain in future, he being still uncured, and to occupy a separate bed. He said if this was to be the case he would leave her; but she rejoined that, if so, she must make clear the reason. Hence this action for separation. And the question asked the Court was whether, under these circumstances, it was obligatory on a wife to permit cohabitation; and, if not, then an order in her favor was requested. Evidence having been taken on the above-mentioned facts, the question put by the Court to many witnesses was, whether the endometritis and other symptoms from which the wife suffered were likely to result from coitus where purulent secretion found its way into the urethra. It was then stated by several medical men that, although there were many causes which produce like symptoms, it was a result quite to be expected under the circumstances. The result of the evidence on his part was to confirm the cause and circumstances of his illness and severe operations, as above described, and the jury (special), after a brief consultation, found that the husband had been 'guilty of cruelty,' which was the legal form of the plaint, and the Court decreed a judicial separation. An appeal was granted. The husband argued the case in person, but the upper Court confirmed the decree of the Court below. No similar case had been in the Divorce Court before, and in any way the decision in its principle was important. It would be difficult to say when the specific contagium of gonorrhœa ceased to infect specifically. In this case a purulent secretion would find its way from the fistula along with the semen, and this would most likely produce irritation of the membrane lining the genital track, with not impossibly salpingitis, cellulitis, etc."

APPOINTMENTS AT OUR CITY LUNATIC ASYLUMS.—The Commissioners of Charities and Correction have appointed Dr. E. C. Dent Medical Superintendent of the Lunatic Asylum on Blackwell's Island, and Dr. A. Trautman Medical Superintendent of the New York City Insane Asylum on Ward's Island. Dr. Dent has filled the place ever since the resignation of Dr. Franklin, to whom he was first assistant, and Dr. Trautman was first assistant to Dr. Macdonald, who has been made General Superintendent.

THE SUIT AGAINST DR. ALFRED S. PURDY AND SON, brought by a patient who had been removed by the Board of Health to the Small-pox Hospital, was, as is generally known, appealed. The Superior Court, General Term, has decided that the complaint should have been dismissed, as there was a reasonable doubt as to the character of her disease in the beginning, and as it was the duty of the physicians to report the case to the health officers, who then assumed the responsibility of taking her to the hospital. We are glad to chronicle this just conclusion of a matter which has been to the last degree vexatious and oppressive to the physicians concerned. The formal decision of the Court, that the responsibility for sending patients to the hospitals for infectious diseases rests with the Board of Health, will be a source of satisfaction to the profession and of safety to the public.

A CHEMICO-PHYSIOLOGICAL INQUIRY.—Two correspondents from Aurora, Neb., write: "Can we have a physiological action of any drug without a chemical action?" Certainly not. All vital phenomena are the expressions of molecular changes in the cells, and such molecular change is "chemical action."

THE LATE DR. FRANCIS M. PURROY.—*Whereas*, It has pleased Almighty God to remove by death one of our number, Francis M. Purroy, M.D.;

Resolved, That the members of the Board of Surgeons of the Police Department of the City of New York hereby express their sincere sorrow for the loss of Dr. Purroy. He was genial in his manner, kind and considerate toward all with whom he came in contact. This Board feels that in his early death it has lost a much respected and most valuable member;

Resolved, That this Board most respectfully tender to the family of Dr. Purroy this expression of their profound sympathy;

Resolved, That a copy of these resolutions be sent to the family of the deceased, and that they be furnished to the medical journals of this city for publication.

CHARLES PHELPS, M.D., *President*.
JOHN H. NESBITT, M.D., *Secretary*.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE AND PATHOLOGY.

Stated Meeting, December 21, 1886.

ALFRED L. LOOMIS, M.D., LL.D., CHAIRMAN.

DR. T. MUNSON COAN read a paper (see p. 38) on

THE THERAPEUTICS OF MINERAL WATERS.

DR. W. H. THOMSON opened the discussion, and said that this was one of the most important subjects in therapeutics. There was one important part of it to which Dr. Coan had not alluded, and that was the contraindication to the use of mineral waters. On account of the fact that these waters increase the interchange of elements and the waste of the body, they were, *ipso facto*, contraindicated in all diseases attended by loss of weight. He would hesitate decidedly before recommending mineral waters to phthisical patients, or to patients who, suffering from nervous affections, were losing weight. With the single exception of diabetes he would not recommend their internal use in any case in which the patient was losing ground in either nervous or muscular power.

There was one significant fact concerning the saline mineral waters of the world, and it was that their constitution was an almost exact reproduction of the watery part of the human blood. Dr. Thomson then compared the Geyser water of Saratoga with pure blood; also Kissingen and others. Patients, while taking these waters, take an excess of the most natural ingredients, and in about the same proportion in which they are found in the blood, hence the action of the system in dealing with this excess is that of a body overfed with a certain kind of food, and in the stimulation of those functions we are to find their therapeutic results.

With regard to classification of diseases in which they may properly be used, he thought that, almost without exception, they could be grouped under the head of disorders of the abdominal circulation. Gastritis, catarrh of the stomach, hemorrhoids, gout, rheumatism, and skin affections in adults dependent upon these diseases, occur in patients with delayed and deficient circulation through the portal system.

In the treatment of diseases of the bronchial, laryngeal, and nasal passages, on the other hand, the use of pure salt was the most efficacious. This group constituted an exception to what he had said concerning the portal circulation, but the use should be in the way of topical applications of pure salt in solution. Nothing was more efficacious for catarrhal affections of the nasal mucous membrane than common salt.

Dr. Thomson had not seen a case of functional nervous disease that had been benefited by the use of mineral waters, and would not recommend them in this class of diseases, unless they had some alliance with gout or rheumatism. In this respect, therefore, he disagreed with the author of the paper as well as with many European physicians.

DR. JOHN C. PETERS had not had very much faith in the efficacy of mineral waters. The simple Hygeia Water was merely aërated distilled water, and contained no mineral ingredients. Yet those who had not compared it with ordinary drinking-water would be very much surprised at the difference. Many dyspeptic patients, especially those who cannot eat fruits and vegetables, can, by the use of this water, escape diarrhœa and increase their diet.

The quantity of soda in the water of the Ems was about one grain to the ounce, but he thought that almost as much benefit could be obtained by the use of waters to which this quantity of soda had been added. Mention was made in a similar way of several other springs. At some of these watering-places the directions given by physicians as to diet were ridiculous and absurd to the last degree.

The Kansas Hot Springs were almost pure water. At Sharon and Richfield hot bran baths have been extensively used. With reference to the purgative waters he thought that about the same results could be obtained by the addition of the same proportion of saline matter to common water, aërated water especially, as could be obtained by the use of Hunyadi and others. What he objected to most was the sending of patients who were unable to bear the expense away to mineral springs with the expectation that they are to receive a special benefit from this mode of treatment.

DR. H. PINKNEY said, concerning Sharon Springs, that he had not seen a single bran bath there, but that they were using the sulphur waters in the usual variety of ways.

DR. PETERS remarked that the bran bath was given at Sharon ten or fifteen years ago, and that certainly it was still used at Richfield.

DR. COAN said that the Hygeia Water was now being prepared so that it was considerably more than simple aërated water. With reference to the use of mineral waters in wasting affections, he had become convinced that they were useful as tonics. In several cases in which there was great loss of flesh, and in which it was still continuing, the gain had been so rapid while using the waters that the effect was unmistakable. He fully believed that the saline waters are tonics. He did not believe that everything could be cured by this class of agents, but believed that more patients could be benefited by them than had perhaps been generally supposed.

DO ANTIPYRETICS AS AT PRESENT EMPLOYED MODIFY THE DURATION OR THE MORTALITY OF TYPHOID FEVER.

DR. S. BARUCH opened the discussion (see p. 33), and was followed by DR. F. P. KINNICUTT, who said that his experience was very much in accord with that of the author of the paper, and therefore he would call attention to only one point. The percentage of relapses during the present outbreak of typhoid fever had been largely in excess of that reported in previous outbreaks in this country, and the question naturally suggested itself whether or not the very generous use of recently discovered antipyretics might be regarded as exercising any influence in increasing this percentage, and therefore, probably, the percentage of mortality.

This was a difficult question to answer, but the same question, it seemed, has been raised elsewhere, as Liebermeister had showed that the percentage of relapses before the use of the cold-water method was nine per cent., while after its introduction it was a little more than ten per cent. Even this difference might be lessened when it was considered that the cases in which relapses occur are very likely to terminate fatally.

During the last three months there had been in the New York Hospital 27 relapses in 40 cases of typhoid fever; and in St. Luke's Hospital out of 18 cases there had been 6 relapses. This percentage is much larger than that recorded abroad. Yet deductions from statistics Dr. Kinnicutt regarded as wholly valueless in determining the influence of antipyretic treatment on the occurrence of relapses. If they positively increase the percentage of relapses, it would not be unreasonable to infer that they interfered with the natural processes of the disease and the expulsion of the poison from the organism.

In 3 of the 6 cases in St. Luke's Hospital in which relapse occurred no antipyretics had been given during the initial attack.

DR. W. H. THOMPSON added the statistics taken from the records of the Roosevelt Hospital for the months of September, October, and November. During these three months 24 cases were admitted.

Of these, relapses occurred in 6, and none of the patients had taken any antipyretic.

Of the 24 cases 6 had antipyretic treatment and 18 did not; but none of the 6 were put upon the antipyretic treatment until the temperature rose above 104° F.

Of the 18 cases only 1 patient died, and he was admitted in convulsions and with symptoms of meningitis.

Two of those treated with antipyretics died; total, 3 of the 24 cases.

The unfavorable symptoms which followed the use of antifebrin in two cases—prostration with profuse sweating, etc.—led him to forbid its use in other cases.

From his experience in the use of antipyrin and the graduated cold bath, he preferred the latter, removing the patient as soon as his temperature approached 102° F., expecting that it would fall considerably after removal from the water.

Dr. Andrew H. Smith mentioned twelve cases that had been admitted to the Presbyterian Hospital since the first of September. In all these cases, when the temperature rose above 103° F., either antipyrin or antifebrin had been administered; they had not been so well pleased with the latter as with the former. There had occurred neither death nor relapse in these cases.

His own feeling was very much like that expressed by Dr. Baruch, that the moderate use of antipyretics in typhoid fever was calculated to tide the patient over a point of danger; but when used recklessly these remedies, competent to do good, may do a great deal of harm.

It had seemed to him that we do not see such cases of typhoid fever as occurred twenty years ago, with black, dry, fissured tongue; sordes upon the teeth; delirium, etc. To what this was due he was not wholly prepared to say.

Dr. Wesley M. Carpenter recalled something of his experience in the treatment of typhoid fever as it occurred in an elevated rural region before the advent of the more modern antipyretic epoch. The treatment was expectant, not quite so thoroughly so as represented by the cartoon referred to by Dr. Baruch, but consisted in the administration of such antifebrile remedies as were in rather common use, as aconite, sal prunella, soda, and ipecac, remedies found in the saddle-bags of the country practitioner, together with fresh air, a reasonable quantity of fluid nourishment, and sponging with cold or cool water, derived from springs or wells, sometimes acidulated and sometimes mildly alkaline. Frequently the patients were visited for days with the administration of only a very small quantity of medicine, never waking them to take it if they were sleeping quietly. Then came stimulants as they were required, and complications were met according to indications. Under such care the rate of mortality was not over ten per cent., and the recoveries included a few cases of hemorrhage from the bowels—all in which the complication occurred. Relapses were almost unknown.

As suggested by Dr. Kinnicutt, it was difficult to obtain the data upon which to base an intelligent answer to the question before the Section, yet he had an impression that the judicious use of antipyretics would be conservative and beneficial, although from his study and hospital observations he did not feel certain that it could be said positively what was meant by the expression "as they are at present used." He had seen patients to whom quinine in thirty-grain doses every hour for three hours had been given, and the temperature fell two or three degrees, but the same amount of decline occurred at the same time in the day without the quinine, so it became a very serious question whether, in those cases, notwithstanding they were brought forward as illustrations of the antipyretic action of the drug, the rather reckless use of antipyretics, mentioned by Dr. Smith, might not have jeopardized the patient's life, although recovery took place.

With regard to heart-failure and degeneration of the muscular fibres of the heart, he had had opportunity, in connection with the pathological department of Bellevue Hospital, to examine microscopically the cardiac muscle in a sufficient number of cases to make it quite evident that it did not occur, at least in the cases that terminated fatally in that hospital, with the frequency one might be led to expect from reading the writings of German observers.

Dr. John C. Peters thought that the internal use of acids had been too much neglected in the treatment of typhoid fever. He believed in the bacterial origin of the disease, and as all the discharges were alkaline they furnished the most favorable fluid for their growth. The use of acids, therefore, was curative. They prevented not only diarrhœa, but hemorrhage, and they could be given by both the mouth and the rectum, varying from muriatic to nitric and sulphuric, as the case might require.

The Chairman said he had brought this question before the Section because it had seemed to him that the time had come for the profession in this city to stop and think as to what they were doing, as it had become the custom, or certainly was a practice too frequently indulged in, to attempt, at all hazards, to reduce a temperature of 102° or 103°—surely 104° F.—by the use of antipyretics; and if one does not accomplish the end, to resort to another.

He had had the feeling for the last two years that we were doing harm by our heroic measures for the reduction of temperature in the treatment of disease. He did not believe that it was possible for any measure which had the power to reduce the bodily temperature rapidly from 106° F. to 100° F. to be used to this extent without danger. He was not certain, for he had been in the line of observation similar to that mentioned by Dr. Carpenter, that failure of the heart is due to parenchymatous degeneration, of which we had at times heard so much, and it had seemed to him to be due to failure in nervous supply as much as to the muscular changes.

One, in speaking to a question of this kind, should speak very carefully, for the reason that we had sprung from the expectant to the heroic plan of treatment; and from the line almost like that to which Dr. Carpenter had referred, we had gone to another extreme perhaps, without questioning whether or not we are doing harm.

While statistics are very uncertain, we gain from cases impressions which go with us in practice. At Bellevue Hospital, from September 1st to October 10th, there were treated in his wards seven cases of typhoid fever, by the use of internal antipyretics as well as external. Of these four of the patients died. From October 10th to December 1st, eleven cases had been treated by the use only of the cold coil to the abdomen when the temperature reached 104° F., and there were two deaths.

In the cases reported by Dr. Thomson antipyretics were used only in the severe cases; and it would not be fair to say that the patients, in the fatal cases, were killed by them, for probably they would have died without regard to treatment. To answer the question, an equal number of average cases must be treated with and without antipyretics. At one time he became convinced that the alcohol treatment was bad in typhus fever, and he became so convinced because he did not give alcohol in bad cases.

A typhoid-fever patient may have a temperature as high as 106° F., and if it does not last but a few hours it is not specially harmful; it is the long-continued high temperature that does harm. When the temperature is 103° F., and lower, most of the day, only a part of the day up to 105° or 106° F., it did not seem to him that such extraordinary efforts as had been sometimes made should be put forth to reduce it. He did not wish to commit himself on the question under discussion, nor did he regard it as wise for any man to do so in the present state of our knowledge. At the same time, he believed that it was well to discuss the subject and endeavor to ascertain whether or not the antipyretic

treatment of typhoid fever had not been carried on a little too strongly.

Dr. A. H. Smith thought if it could be proved that the internal use of antipyretics in any way checked the production of any morbid material to the presence of which high temperature is due, then, by the administration of such drugs, we were striking directly at the root of the evil.

Dr. Kinnicutt remarked that it was somewhat suggestive that all our most powerful antipyretics were taken for the class of antiseptics.

Dr. Thomson said that, on the other hand, experience at Roosevelt Hospital had shown that the temperature in all the fatal cases might not reach 104° F. This was the experience in 1884, when there were nine fatal cases in the months of August and September, and it showed that mortality did not depend exclusively on temperature.

With regard to the internal administration of antipyretics, his objection was that all of them, thus far, had been derived from the phenic-acid series, every one of which was a cardiac depressant. Quinine belongs to the same group.

Dr. Baruch said that in opening the discussion he had offered his personal views, derived from a general impression, regarding the influence of antipyretics on the mortality of typhoid fever. He was, however, glad that he could cite Gutmann's views in support of his own. Recently Ebstein had reported 337 cases treated without antipyretics, and had found that the duration of treatment was 49.4 days, while the average of 846 cases treated in the Berlin City Hospital, Moabit, with antipyretics was 39.4 days, making a difference of ten days in favor of the antipyretic method so far as duration of the disease was concerned. These were the only statistics that had come under his observation. Gutmann refers to the difficulty of obtaining accurate information regarding the effect of antipyretic treatment on the mortality of typhoid fever on account of the variations in the type of the disease; but he is satisfied that the mortality, which before the introduction of antipyretics was averaged by Griesinger as about twenty per cent., had been greatly reduced. The mortality of the 846 cases in the City Hospital, Moabit, averaged in nine years about thirteen per cent. Liebermeister, in his latest work in "Ziemssen's Cyclopædia," just published, says that the mortality has been reduced fifty per cent. since the advent of the antipyretic method.

After nominating Dr. E. Darwin Hudson, Jr., for chairman, and Dr. R. C. M. Page for secretary, the Section adjourned.

SECTION IN OBSTETRICS.

Stated Meeting, December 23, 1886.

Alexander S. Hunter, M.D., Chairman.

Dr. E. L. Partridge read a paper on

THE USE OF ANÆSTHETICS IN LABOR,

based chiefly upon personal experience. Shall an anæsthetic be used in labor? If so, under what circumstances, and what agent should be employed? He believed that one should almost invariably be used where an operation was to be performed, and it might be used with propriety in a great many natural labors. He would not use it in the first stage, except in so-called forced labor, or labor hurried by artificial means, as Barnes' dilators, etc. He would avoid the use of an anæsthetic in the early part of the second stage, because it does, to some degree, modify uterine action. He would wait for the suggestion of the patient before using an anæsthetic to relieve the pain. If he had no particular reason for using it, he would never urge its use. It is not necessary to produce full anæsthesia in order to lessen the woman's sufferings, and it is only as the child is about to be born that he carries the anæsthesia to the extent of rendering the mother unconscious. If the woman be phlegmatic, or is one who has herself under control, he would not employ an anæsthetic in normal labor. During obstetric operations an anæsthetic should always be employed. Except in placenta prævia and prolapse of the funis, he would use an anæsthetic in version.

After speaking of some of the objections that had been urged against the use of anæsthetics in labor, as its immorality, the liability of performing operations in a bungling manner, etc., the speaker said he could conceive that the liability to the occurrence of post-partum hemorrhage would be a little increased, while the liability to the occurrence of puerperal fever would not be increased, unless violence be used during the operation. Subinvolution and chronic uterine disease might possibly be a little more likely to occur after the use of an anæsthetic.

With regard to the kind of anæsthetic to be used, theoretically, he was unable to see how *cocaine* could do any good, and he had failed to obtain any benefit from its use practically. He would never use *chloroform* in general surgery, and would have but little sympathy for the surgeon who should lose a patient from this anæsthetic. In obstetrics, however, he uses chloroform usually; at the same time remembering that its use is attended with a certain degree of danger. Women have died from the effects of chloroform during labor, but in almost all such cases it has been administered carelessly.

He then gave the differences in the conditions of the surgical patient and a woman in labor, and then spoke of the advantages of chloroform over ether.

In the administration of chloroform he never uses a cone, but simply a folded handkerchief upon which has been put a few drops of the anæsthetic, and it is then held from an inch to an inch and a half from the nose. A crumpled handkerchief in the bottom of a whiskey glass or small tumbler makes a very convenient apparatus.

He would not feel that it was safe to give chloroform to a woman who was already considerably under the influence of chloral. An objection to chloral in the first stage of labor was that the accoucheur must wait until its influence had passed off, and thus it might interfere with the use of chloroform in the second stage.

He believed it to be proper to combine nitrite of amyl with chloroform (the former being an antidote to poisoning by the latter), in the proportion of ten drops to the ounce.

He would never administer any anæsthetic without the consent of some other person than the woman who was in labor.

Dr. Malcolm McLean was ready to indorse Dr. Partridge's views almost entirely. He does not employ any anæsthetic in obstetric practice except chloroform. He uses it in normal labor, when the head begins to distend the soft parts, and had found that it not only allayed pain, but stopped the violent expulsive efforts which might produce lacerations.

Dr. Paul F. Mundé uses chloroform. He does not think it necessary in normal labor to put the woman into the condition of entire unconsciousness, except, perhaps, for two or three minutes when the head presses the hardest, and is passing over the perineum. He does not believe in the use of chloral. One very important point was, never to raise the woman up until she had fully recovered from the influence of the chloroform.

Dr. H. T. Hanks uses chloroform. He avoids any anæsthetic in the first stage of labor. He does not give chloroform simply because the woman desires it. He has used paraldehyde with good effect. He would use chloroform where all other means had failed to produce dilatation; frequently, for purposes of diagnosis, especially in primiparæ with slowly progressing labor and unduly sensitive soft parts; also when the head is passing the perineum; and where the forceps must be used, or a surgical operation or version is to be performed. He uses ether in preference to chloroform when he expects

to keep the woman under the influence of the anæsthetic more than one hour, and also in very anæmic patients.

Dr. W. R. Gillette uses chloroform. He regards the management of the first stage as more important than that of the second. He uses chloroform in all cases of delayed first stage, for its effect in overcoming muscular obstruction before the second stage begins. He gives chloroform, therefore, in the first stage, and assists it by manual dilatation, and by so doing he was confident that he had shortened the labor and also diminished the number of forceps cases. Nor was he afraid to administer it to the surgical degree. In its use, however, the obstetrician must be guided by the peculiarities of each individual case. In the latter part of the second stage he always gives it to the production of the surgical degree of anæsthesia. His method is to use a crumpled handkerchief in the bottom of a whiskey-glass which does not fit over the patient's face tightly, and which can be easily turned bottom side up upon the pillow or a plate, and thus prevent the escape of chloroform that sometimes produces such disagreeable sensations upon the attendants. He is guided solely by the respiration in its administration. He had never seen any danger from post-partum hemorrhage on account of the use of chloroform. Nor did he think that it made very much difference whether chloroform or ether was used in obstetric practice. Our Boston friends use ether. He would use an anæsthetic in all operative cases and would leave the case, under those circumstances, if neither the patient nor the friends would submit to its administration.

Dr. S. T. Hubbard had not been in the habit of giving chloroform as often as some had in obstetric practice. This question came up for discussion in the Academy about thirty years ago, when it was learned that several had never given it, while others had given it to the surgical degree, and some gave it in every case of labor. Among the old doctors the practice, before the days of chloroform, was to bleed and give an anodyne in delayed labor, and it was very good practice. Nowadays, if his patients want chloroform he gives it to them in the second stage of labor, while the head is pressing upon the perineum; if they do not say anything about it, he does not; and some women refuse to take it, saying that they wish to know it when they have a baby. It is important, however, in many cases, to give it, and he thought that the indications had been fairly pointed out in Dr. Partridge's paper. He thought there was some danger of post-partum hemorrhage due to the anæsthetic, and he thought, also, that the woman, as a rule, did not recover so well after the use of an anæsthetic as when labor was completed without it. Early in labor he preferred to give his patient an anodyne; possibly bleed her. At all events, the success in obstetric practice was about as good among the old doctors who practised that method as it had been at any time.

Dr. H. J. Garrigues makes use of chloral, with but few exceptions, in every case of labor. When the os does not dilate well, and there is considerable pain, he gives it at intervals of half an hour until the patient sleeps. Sometimes he uses, under the same circumstances, morphia or opium. He never uses chloroform in the first stage of labor, and far less nowadays in the second stage than formerly, and he would be glad if he could do without it; many women did not ask for it and he did not look for indications in order to propose it. It protracted labor and was of considerable danger with reference to post-partum hemorrhage.

As soon as he has to perform a considerable operation, as the use of the forceps, etc., he uses ether, unless there are contra-indications.

There are two very important

CONTRA-INDICATIONS TO THE USE OF ETHER

—namely—(1) The slightest quantity of albumen in the urine, and (2) the presence of any affection of the lungs.

Dr. R. A. Murray uses chloroform, and believed that it was of the very greatest service in the first stage of labor. If the first stage was properly managed, the second stage would go along all right. There were many conditions in which only a slight degree of anæsthesia was required to relax and improve the condition of the soft parts. In the cases in which there was a straight sacrum and an undilated os, and the pressure upon the nerves was great and attended with cramps in the legs, the administration of chloroform was beneficial.

He had not seen any bad effect produced by chloroform with regard to post-partum hemorrhage, but thought that a great many children were lost when it was carried to the surgical degree. When heart disease was present, ether was preferable to chloroform, because it stimulates the heart. Chloroform should absolutely be withheld in cases of placenta prævia, but ether can be used with advantage.

Dr. H. C. Coe rejected cocaine entirely in obstetric practice. With reference to heart disease as a complication of labor, it was more frequent than might be supposed, as he had found mentioned five hundred cases by French writers, and in a great many of these death occurred. Charpentier leaves the question undecided whether or not anæsthetics should be given under such circumstances. Dr. Coe would hesitate very much before using anæsthetics in cases where the complication was present. He did not think that the respiration could with safety be the only guide concerning danger while the anæsthetic was being used, but believed that the pulse as well should be closely watched. He had used the A.C.E. mixture in a large number of cases in Vienna without any deleterious results.

Dr. John C. Peters had used ether mostly, and began its use back in the "roaring forties." When he uses chloroform he does not put the patient fully under its influence, except for the use of the forceps or an operation of equal severity.

Dr. Partridge thought that it was important not to lift the patient up after an anæsthetic, as referred to by Dr. Mundé. He agreed that the first stage of labor should be properly managed, as it might be too prolonged, etc., but thought it did not necessarily follow that chloroform was the agent to be employed. It was a matter of individual experience whether chloroform or some other agent should be used. He preferred an anodyne, as morphine or chloral, for the reason that he did not like to commence chloroform early, as when begun early it was impossible to discontinue it.

After the nomination of Dr. E. L. Partridge for chairman and Dr. L. Emmett Holt for secretary the Section adjourned.

A New Hospital in Detroit.—The *Medical Age* indulges in a little smile at the expense of some physicians of Detroit who exerted themselves to persuade the public that there was need of a new hospital. Their efforts succeeded beyond their expectations, for the land for a site has been donated and two gentlemen have contributed $100,000 each toward the erection of the structure. Thus far the philanthropic physicians were doubtless well satisfied with the results of their efforts in behalf of the sick poor, and were glad to think that they had been instrumental in the foundation of a great, though not much needed, charity. The only thing to mar their joy, however, is the fact that the new hospital is to be placed exclusively in charge of the homœopathic practitioners of that city.

Nitrite of Amyl as an Antidote to Opium.—A case is reported in *L'Union Médicale* of a person who took two ounces of laudanum, and showed every symptom of opium poisoning—coma, small pulse, feeble and infrequent respiration (six to the minute), coldness, and cyanosis. Belladonna proved useless, while inhalations of nitrite of amyl were followed by immediate improvement, and the patient ultimately recovered.

Correspondence.

WILL THE PRESENT LEGISLATURE CODIFY THE LAWS REGULATING MEDICAL PRACTICE IN THE STATE OF NEW YORK.

To the Editor of The Medical Record.

Sir: It is worth while at this moment to call the attention of medical men in this State to what improvements in the laws regulating the practice of their profession they may obtain, by concerted action, from the Legislature about to convene.

Many physicians think that the defeat of every bill introduced of late years to create a State board of medical examiners signifies an unwillingness of legislators to improve the sadly confused laws now in force. On the other hand, not a few legislators have come to believe that it is not possible for doctors to agree on any point; and when asked to introduce a medical bill they begin with one accord to make excuses, on the ground that their time would be consumed in fruitless discussions.

A clear understanding of the facts in the premises will show that there is here misunderstanding on both sides, and that a law can be enacted which will purge the statute-book of its present confusion, greatly improve the state of medical legislation, and meet with the approbation of all reputable men and practitioners of medicine, except those who honestly believe that all health-laws and laws regulating trades and professions are wrong in principle.

Permit me, therefore, to point out:

First, why the bills to create a State examining board have failed to become law; while their discussion has made many legislators think it impossible to frame any bill on which practitioners of medicine will agree; and

Second, the points upon which agreement is possible, and legislation, therefore, obtainable; together with the advantages to be hoped from such legislation.

In the first place, then, why have the bills creating a board of medical examiners failed to become law?

In the session of 1885 there were three bills introduced creating a board, or boards, of this kind. One was introduced at the instance of the Medical Society of the State of New York. It provided for a board of nine members, of whom six were to be chosen from that society's nominations. A second bill, favored by the homœopaths, provided for the organization of several distinct boards. A third, commonly known as the Heath Bill, because introduced by Mr. Heath, of the Assembly, provided for a single board, made up of three regular physicians, three homœopaths, and three eclectics. The partisans of any one of these bills opposed the others. The Medical Association opposed them all. The committee-rooms became like "the ringing plains of windy Troy." The clashing interests were irreconcileable. Compromises were proposed and rejected. Legislators were button-holed and snowed under with letters pointing out, not the merits of any one of the bills, but the demerits of two; to them there appeared to be a consensus of opinion that all were bad, and no counterbalancing testimony to the excellence of any one. It is needless to detail the arguments of the various friends and opponents of these measures; suffice it to say that the homœopaths and eclectics contended that the board created by the bill of the Medical Society of the State would be a Moses' rod to eat them up. The society's committee maintained their right to a numerical ratio of representation, and claimed that with several boards the standard of license would be that set by the poorest. The law-makers refused to enact any of the bills.

In 1886 about the same ground was ploughed over. But during that session a bill to repeal the law of 1880 and restore the law of 1844, which our Supreme Court dubbed the triumph of quackery, was easily defeated, showing that the temper of the Legislature was not in favor of licensing ignorance to prey on the community.

So much for the disagreements; *all on the point of organizing the licensing board.*

Second, in all the bills above referred to there were provisions looking to the regulation of unlicensed practice, and constituting a great and important part of each; these provisions were substantially the same, and almost *ipsissimis verbis* in each bill. Toward the close of the session of 1885, when all the bills to create examining boards were dead, I drafted a new bill [1] embodying the points of agreement of all the others. It passed the Assembly with about three dissenting votes. In the Senate it was on its passage when the chairman of the Judiciary Committee, misunderstanding a phrase as to the burden of proof, and not having read the bill, objected to the present consideration when it was called. There were but two or three days of the session left; the objection was fatal, and the bill died for lack of opportunity to be discussed on its merits.

Last year, after the death of the examiners' bills, and of course at the close of the session, a similar bill [2] was again introduced. Dr. Paine, chairman of the Homœopathic State Society's Legislative Committee, after careful examination of its provisions, supported it; the counsel of the Eclectic College and Society in this city appeared before the committee, but did not oppose it. In the Senate it passed. In the Assembly it failed to reach a vote before adjournment.

At the recent meeting of the Homœopathic State Society they instructed their Legislative Committee to oppose all bills to create a single board of examiners, to favor making the regents' examinations compulsory, and to favor a bill substantially the same as Senate Bill 485 of last year, of which their committee say in a printed statement for distribution among their county societies: "Its essential provisions being in the main founded on correct principles, few members of the profession of either school will interpose any objections thereto; on the contrary, will, so far as may be in their power, endeavor to promote its passage."

It is scarcely prophesying to say that this bill, made up of provisions from the bill introduced by the Medical Society of the State, commended by the Homœopathic State Medical Society, tacitly assented to by the eclectics' representative in open committee, and passed by the Assembly of 1885 and by the Senate of 1886, will become a law if proper action is taken in its behalf.[3]

It only remains, now, to examine in what that bill differs from the law of 1880, which, in spite of all that has been said to the contrary, has proved to be the best law of the kind yet passed in this State, and to point out why its enactment is desirable. For this purpose the deadly parallel column may be used, but with no intent to disparage the law of 1880, which itself has been, as already said, a step in advance of what legislation preceded it.

Provisions of Chapter 513, Laws 1880, as Amended by Chapter 411, Laws 1884.	Provisions of Senate Bill 485 (Assembly 903), Session of 1886.
Section 1. A person shall not practise unless twenty-one years of age and authorized so to do, either before the passage of the act, by the laws in force at the time of his authorization, or after its passage, by Chapter 746, Laws 1872, or Chapter 513, Laws 1880.	Sections 1 and 2 repeat the provisions of the Revised Statutes and Laws of 1880 making a diploma after three years' study a prerequisite of license. They effect no substantial change in the purpose of the law, and preserve existing rights.
Section 2 requires registration of all practitioners (and was intended to make false affidavits by unqualified persons a perjury, but	Sections 3, 4, and 5 provide for registration, and prescribe certain formalities to correct the evils of reckless registration by county

[1] Assembly No. 820, introduced by Mr. Van Duzer, April 22, 1885. Senate No. 419, introduced by Mr. Robb, April 24, 1885.

[2] Assembly No. 903, introduced by Dr. Craft, April 7, 1886. Senate No. 485, introduced by Mr. Connelly, April 7, 1886.

[3] I am purposely guarded in my expressions as to the eclectics: for, while I did not understand their only representative before the committee to oppose the bill, to parts of which he expressly assented, it is still true that their State society joined in the clairvoyants' attempt to repeal the law of 1880, less stringent than the proposed measure, and circulated a memorial for that purpose.

fails to do so by reason of its phraseology).

Section 3 makes it a misdemeanor to practise without authority, or for one possessed of authority not to register, or to practise under a diploma "unlawfully obtained" (a vague phrase).

Section 4 permits a person from without the State, with a diploma from an incorporated university, medical college, or medical school, to practise after indorsement of the diploma by an incorporated medical college or medical school of the State and registration; provided (by amendment of 1884) that this section shall not apply to physicians of bordering States, whose practice extends over our border, so long as they do not open offices in this State.

Section 5 makes the degree of M.D. lawfully conferred by an incorporated medical college or university of this State a license after registration.

Section 6 exempts commissioned officers of the United States Army, Navy, and Marine Hospital Service, and persons in practice ten years who were matriculated in medical colleges of the State at the passage of the act and graduated within two years thereafter.

Section 7 repeals all inconsistent acts and parts of acts.

clerks of invalid diplomas or their indorsement by colleges.

Sections 6 and 7 define "practice of medicine," and make it a penal offence for one to practise after conviction of felony, or without authority or registration, or under authority illegally obtained; make the purchase, sale, fabrication, and imitation of diplomas, or obtaining diplomas by misrepresentations of fact or swearing falsely to any affidavit required by the act, or practising under an alias, or falsely personating a practitioner, illegal; and enact the rule as to burden of proof as laid down by the courts.

Section 8 gives to incorporated societies a civil action for a penalty against irregular practitioners, forbids them to bring actions to recover fees, and allows anyone who has paid them fees to recover twice the amount paid and a penalty.

Section 9 exempts from the purview of the act United States medical officers and members of hospital staffs in actual service; also dentists exclusively practising dentistry; and qualified practitioners of other States, whose practice extends over the New York border, but who have not offices in this State; and persons duly qualified in one county, attending occasional isolated cases in another, but not regularly practising therein.

Section 10 specifically repeals all acts in *pars materia*.

Schedules A, B, C, and D prescribe forms of affidavit, indorsement, and certificate of registration.

It will be seen from the foregoing that except for the specification of new offences the two acts cover the same ground; but the greater detail of the proposed bill may be best inferred from the statement that it, with its schedules, covers thirteen pages, whereas the act of 1880 would cover about two. In the case of The People vs. Kahn the court held that under existing statutes a diploma from the president of a college faculty was not invalid in the meaning of the statute, even if the signature on it had been forged or fraudulenly obtained by him. As the law stands, the purchase, sale, and counterfeiting of diplomas either constitute no offence or are illegal only when shown to be part of the false pretences by which money has been fraudulently obtained. Men convicted of criminal malpractice come out of the penitentiary and openly advertise their criminal business in the columns of the daily press. Dead men are personated by the purchasers of their diplomas. False swearing in registration by unlawful practitioners does not constitute perjury. The proposed bill essays to perfect the criminal law in these regards, and by giving a civil action to afford the prosecution an opportunity in certain cases of foreigners with forged papers to issue a commission to foreign countries; a thing they cannot do in a criminal proceeding.

It is safe to say that no reputable man will care to oppose vigorously a bill punishing offences all of a fraudulent character.

In the next place, the bill provides one simple statute in place of several of doubtful validity, and codifies the laws.

Finally, by enacting all that the various parties in interest can agree upon, it leaves a fair field and a clear-cut issue for future legislation as to the standard of medical education. The friends of central boards argue forcibly that the diploma, as a standard, has only the value given it by the poorest "diploma-mill" conferring or indorsing it. The friends of a central board argue in like manner against many boards. Colleges stand up for what they claim are their vested rights. Regular physicians demand to be represented in a single board according to their numerical preponderance over those who designate their practice by special names, or else oppose any legal recognition of the fact that there can be "schools" in medicine. Homœopaths and eclectics claim that a single board means their extinction as distinct bodies of practitioners.

An issue so many-sided as this needs to be made clear and precise, and freed from all merely collateral discussion. The quicker this is done the sooner it will be settled. But meantime it seems a pity to sacrifice the bird in the hand by striving to catch the bird in a particularly thorny bush; especially when it seems so easy to tie the former securely and then to explore the bramble-bush with all the joy of a pachyderm.

I am, Sir, your Obedient Servant,

W. A. PURRINGTON.

63 WALL STREET, December 24, 1886.

THE END OF A CURIOUS MALPRACTICE SUIT.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I have just had the pleasure of a verdict in my favor in a malpractice suit for $10,000, and thinking that the case, which was somewhat unusual, might be of general interest I send you a brief history of the case and trial.

In April, 1884, I was called upon to treat Mrs. Thomas Bermingham. I found her suffering from hip disease in the second stage. I placed the patient at rest, with weight-and-pulley extension. The family were very poor, and unable at any time to purchase a portable apparatus. In October, 1884, I made an exploratory incision through the skin and superficial fascia on the anterior surface of the thigh, some four inches below Poupart's ligament, upon a little swelling like the small end of an egg. Not reaching anything I went no deeper. At the same time, while the patient was under ether, I made passive motion of the thigh to see whether the anchylosis was osseous or fibrous; it proved to be fibrous, and the adhesions were somewhat broken up. The patient did well, and within three weeks walked, without my knowledge, about three miles. I withdrew from the case late in October. The patient was not under any treatment till March, 1885, when the attending physician discovered that the thigh was twenty-four inches in circumference, when fourteen or sixteen would have been normal. He secured a portable apparatus, and expected, as he testified, recovery.

I saw her in March, 1886, and found her apparently dying, emaciated, suffering extreme pain; her thigh thirty-four inches in circumference, purple, coursed over with veins, and ready to bleed at touch almost.

She died March 10, 1886, and the femur was found of normal size; the head necrosed and entirely separated from the shaft, and not a drop of pus present. (There never had been an abscess.)

The attending physician, Dr. Beckett, testified that my incision must have been two and a half inches long and two or three inches deep, and that the tumor of the leg was a multiple fatty tumor, due to the incision. I proved by physicians who saw the tumor, and by others who testified to its character from description, that the tumor was a sarcoma, and was the cause of her death. The jury were out five minutes.

R. M. STONE, M.D.

OMAHA, NEB., December 20, 1886.

SALICYLIC ACID IN JAUNDICE.—Bartholow says that when the cause of jaundice has been removed salicylic acid will remove the bile-pigment from the blood more promptly than any other drug.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 25 to December 31, 1886.

KOERPER, EGAN A., Major and Surgeon. Granted leave of absence for two months, to take effect about January 1, 1887. S. O. 297, A. G. O., December 27, 1886.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Granted one month extension of his leave of absence. S. O. 297, A. G. O., December 27, 1886.

Official List of Changes in the Medical Corps of the United States Navy for the week ending January 1, 1887.

ANDERSON, F., Passed Assistant Surgeon, to U. S. S. Thetis.

AUZAL, E. W., Assistant Surgeon. Detached from R. S. Independence, and ordered to Coast Survey Steamer McArthur.

GREEN, E. H., Passed Assistant Surgeon. Detached from Naval Laboratory for temporary duty on R. S. Independence.

GATEWOOD, J. D., Passed Assistant Surgeon, to Naval Academy, January 5, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau. Health Department, for the week ending January 1, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	18	7
Scarlet fever	30	3
Cerebro-spinal meningitis	4	4
Measles	468	63
Diphtheria	104	40
Small-pox	0	0
Yellow fever	0	0

SURGICAL ANTISEPSIS IN THE BULGARIAN WAR.—In one of the last numbers of the *Archives de Médecine Militaire*, M. Audet gives a brief surgical history of the Serbo-Bulgarian War. Of three thousand wounded men carried to Belgrade Maydl reported fifty-one deaths, twenty-two of which were due to tetanus, leaving a direct surgical mortality of less than one per cent. Iodoform dressings were used, and there was not a single case of erysipelas, notwithstanding that the sanitary and moral surroundings of the wounded were very bad. Of two hundred wounded, Schmidt reported three deaths only; there were four cases of traumatic erysipelas, but none of gangrene or of pyæmia. Dressings of iodoform and corrosive sublimate were used. At Sophia the wounded were received in a pronounced septic condition, but the same favorable results were obtained by antisepsis. Notwithstanding the lack of care on the battlefield, of one hundred and thirty-six cases of injuries, many of which were wounds of bones or articulations, reported by Dr. Blum, there was no case of pyæmia or erysipelas. Iodoform gauze was used in these cases. Similar favorable results were reported by other surgeons in the field, and a comparison of these statistics with those of like injuries a few years ago leaves little room to doubt the value of antisepsis and cleanliness in the treatment of wounds.

OUR FOREIGN-BORN CRIMINALS.—Over one-half (fifty-two per cent.) of the criminals of this State are foreign-born; nearly one-third are Irish and one-tenth are German.

A MEDICAL SCHOOL IN FORMOSA.—Dr. Wykeham Myers, of Takau, in the Island of Formosa, has begun a work which promises to be of extended usefulness. It is the establishment of a school for the education of natives in medicine and surgery. The curriculum is a full one, and the standard of efficiency, as shown by the questions set and answered, is evidently high.

NAILERS' CONSUMPTION AND THE TUBERCLE BACILLUS.—Dr. James E. Reeves, of Wheeling, W. Va., has observed in exceptional cases only the bacillus tuberculosis in the sputum of what is called nailers' consumption. The pulmonary diseases so frequently observed in persons engaged in the nail mills are seldom tuberculous. The same may be said of the coal miners.—*Progress.*

A SIGN OF DEATH.—Among the means of determining between actual and apparent death, M. Peyraud regards cauterization of the skin by Vienna paste as one of the most certain. In the living subject the eschar formed will be of a reddish black or brownish color, while in the cadaver it is yellow and transparent. If the eschar is formed slowly and is of a yellow color, the subject is dead, but if it is red, brown, or black it may be assumed that life is not yet extinct.

THE TITLE OF DOCTOR was invented in the twelfth century, at the first establishment of the universities. William Gordenia was the first person upon whom the title of Doctor of Medicine was bestowed. He received it from the college at Asti, in 1329.—*N. Y. Med. Times.*

THE INTERNATIONAL CONGRESS AND THE PREVENTION OF TROUBLE IN THE FUTURE.—In a notice of the organization of the International Congress, in *L'Union Médicale*, M. L. H. Petit says that it cannot be denied that the profession in this country is very imperfectly represented in the list of officers, and expresses a natural regret that such is the case. The great advantage of medical reunions of this nature, he writes, is that they bring together men who are for the greater part known to each other only by their writings. And if the Americans best known abroad are not to be present, the main object of the congress will not have been accomplished. Without doubt the pleasures of the voyage, of the various excursions, and of visits to the large cities in the neighborhood of Washington will suffice to draw many Europeans across the Atlantic, but, he asks, will the picturesque side cause the scientific side to be forgotten? The remedy for such unfortunate family quarrels which the writer suggests is, that the organization of future congresses be intrusted to a permanent committee composed of men of every country. The members of this committee should be elected at the final session of one congress, and should be retired only after the committee on organization of the succeeding congress should have been definitely constituted. In other words, the affairs of the International Congress should be controlled by the members of the congress, and not by a local organization which may or may not represent truly the medical profession of one country. M. Petit suggested this plan at Copenhagen, and signifies his intention of introducing the measure again at Washington in 1887.

A PECULIAR METHOD OF GYNECOLOGICAL EXAMINATION.—Omaha seems to have a gynecologist whose methods are decidedly unique. He has a large, unwashed old dress of his wife's in his office, and all patients are directed to remove every article of clothing and then to don this dress preparatory to ascending the table. While on the table no effort to prevent exposure is made. All his patients are compelled to receive local uterine treatment daily and straight through the menstrual period as well.

Perhaps he is a Fraud.—A recent cable letter to one of the daily papers says that Dr. Succi, who has been amusing a credulous public by exhibiting himself in a fasting condition, is reported to be an impostor rather than foolish. A buxom young woman, the mother of a fine boy, is in attendance upon the faster, and it is asserted that she divides the secretion of her lacteal glands with great impartiality between the scientist and the infant.

Voudooed Pillow.—A writer in the *New Orleans Picayune* tells how he met a colored woman who attributed her husband's illness to his sleeping on a "voudooed pillow." She felt the pillow and discovered the "voudoo," which felt hard. The pillow was carried to the river, cut open, and the feathers cast into the water over the left shoulder. If they assumed the shapes of animals as they floated away, the sick man would get well. In a subsequent interview this sable lady informed the writer that the feathers floated off as dogs, cats, etc., and her husband was well.—*The Lancet-Clinic.*

A Strange Meeting.—Not long ago a gentleman was run over in the street, in London, by a cab, and was carried into one of the hospitals and put to bed. Shortly afterward one of the house-surgeons went to attend to the case and found that it was his own brother.

Plain Wall-paper for the Sick-room.—In a recent lecture on nursing, Miss Kelman illustrated the need of having the walls of hospitals of a quiet and unobtrusive color, by telling an anecdote of a patient—an old gentleman—who was heard continually muttering, "Fourteen up, thirty-five across." This fact arrested the attention of the doctor and nurses, who examined the room, and ultimately found that the pattern of the paper was divided into squares of fourteen up and thirty-five across. When the old gentleman fell asleep, he was quietly removed to another room, where, the wall-paper being of a neutral tint, he quickly recovered.—*The Hospital.*

The Third Scourge of Humanity is what Erlenmeyer calls cocaine, alcohol and morphine being the other two.

Galazima is the name of a new milk-preparation of the nature of kumyss and kephir. It is prepared by mixing four grams of good grain-yeast in a little water, and adding this and ten grams of cane-sugar to a litre of milk, hermetically sealing the bottle, and then shaking the mixture. At the end of twenty-four hours the galazima is ready. It is described as a pleasant and nutritious beverage, containing one per cent. of alcohol, and heavily charged with carbonic acid gas.

Treatment of Obesity.—Professor Albert Robin, from a long discussion and study of the subject, concludes that, in cases of obesity, if there be a small excretion of urea, fluids should be freely administered; but if there be an excess of urea secretion, fluids are to be avoided.

The Guild of St. Luke.—A correspondent writes that this organization is not a Catholic society, as would seem to be implied by the statement of its object. It is an association formed of medical men, clergymen, and artists, members of the Protestant Episcopal Church, who pledge themselves to uphold the doctrines of Christianity and to promote the spread of the faith by prayer and the force of personal example.

An Enterprising Quack.—A story is going the round of the papers to the effect that a quack in St. Louis guarantees to cure almost any disease for a good round sum, which must always be paid in advance. Of course he often fails, and then the patient wants his money back. The "doctor" employs a lawyer for just such emergencies, and pays him $5,000 a year salary. The lawyer is so skilful in pacifying angry patients and compromising with implacable ones that the "doctor" is able to make about $8,000 a year above all expenses.

A Specialist on Specialism.—Those of us entering practice twenty years ago found men plying medicine as a trade, regarding patients as the physician's private property, not to be trespassed upon by strangers, often controlling such patients by appeals to their ignorance, fears, and prejudices, and substituting in their own persons an acquaintance with the weaker side of human nature, useful for financial purposes, for an exact scientific acquaintance with disease, to be used for the benefit of their race. The specialist was the pioneer into this latter realm, and, like all such, was, too frequently, a martyr to his cause. But he represented that majority which consists of one with truth upon his side, and, like all other such majorities in the history of the world, he has finally won his way to victory. The "elaborate division of labor" is "as useful and successful in a learned profession as it is in the mechanic arts," for the whole matter is a relative question of height of standard. General medicine itself is too often only special attention to such diseases as may prove rapidly fatal; and neglect, or often worse than neglect, of all other maladies. It is itself merely an abnormal, ill-defined specialism, substituting multa for multum, and, like the young cuckoo, insisting upon the sole control of its illegally held habitation. Specialism substitutes quality for quantity, which substitution is the distinguishing mark of the civilized man from the savage; nay more, the essential criterion of advancement in civilization itself.—Dr. Edward Wigglesworth, *Trans. of Amer. Dermatological Association, Presidential Address.*

Disinfection of Cabs.—The St. Giles Board of Works, in London, have announced that hackney carriages which have been used for the conveyance of persons suffering from infectious disease will be disinfected by the board free of charge, and that the driver may be supplied with a certificate of such disinfection by applying to the medical officer of health.

Females and Women.—Dr. Williamson protests, in the *British Medical Journal*, against the common employment of the word female when woman is meant, and calls the editor to task for publishing a paper on "Some Functional Disorders of Females." He regards that subject as one covering altogether too much ground to be discussed in a short paper, and thinks it would have been better if the writer had called his paper one on disorders of women. Seeing the title, he says he read the article, expecting to find it a study in comparative physiology.

The Death-rate in St. Petersburg is said to exceed the birth-rate by nearly one hundred a month. The city is growing, nevertheless, by reason of the constant flow toward it of the country population. The excess of deaths over births is owing partly to the presence in the city of large numbers of soldiers whose wives and families have been left at home.

Contraindication to the Use of Paraldehyde.—Sommer concludes that paraldehyde ought not to be given to patients presenting atheromatous defects, and should not be employed in connection with alcoholic liquids. Eickholdt holds that the presence of vaso-paralytic symptoms precludes the employment of paraldehyde.

An Oleomargarine Bill in Denmark.—The Minister of the Interior in Denmark has found it necessary to lay a bill before the Folkething regulating the trade in artificial butter. If his bill be carried, dealers will be compelled to pack such "butter" in cases marked "margarine." As no mention is made of any provision in the bill compelling the retailer to state to his customers that he is selling butter, it is to be feared that consumers will not benefit to any great degree.

PERIPHERAL NEURITIS AND THE PAINFUL PARALYSES OF EARLY LIFE.[1]

BY HENRY DWIGHT CHAPIN, M.A., M.D.,

PROFESSOR OF DISEASES OF CHILDREN AT THE WOMAN'S MEDICAL COLLEGE OF THE NEW YORK INFIRMARY, LECTURER AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

THE scarcity of autopsies in comparison to the frequency of paralysis in early life has rendered this affection difficult to study accurately. A careful observation of symptoms, interpreted by our increased knowledge of the anatomy and physiology of the central and peripheral nervous system, is, therefore, very essential in the study of the disease. There have come under my observation certain cases that have puzzled me in endeavoring to fit them in with the usual classification of the text-books. There has been an atrophic form of paralysis, that in inception, development, and result has differed from the spinal paralyses with which I have been familiar. The essential paralysis of Rilliet and Barthez, assuming an absence of structural lesion, and the myogenic theory of Bouchut, have, on the strength of microscopic examinations, given place to the idea of the spinal source of the trouble. When we consider, however, that most autopsies have been made years after the inception of the trouble, when death has taken place from some other cause, and that there have been relatively few autopsies made in proportion to the number and variety of the paralyses, there seems rather a slender basis for the theory of an exclusively spinal paralysis in childhood. In most of the examinations that have been recorded, investigation of the spinal cord only seems to have been made, and not of the peripheric nerves. In the complete table of autopsies collected by Dr. M. P. Jacobi, in "Pepper's System of Medicine," Laborde's case is mentioned, in which an infant of two years, who had been paralyzed over a year, was found to have sclerosis of the antero-lateral columns with normal ganglion-cells and a sciatic neuritis. There is also one case cited where a microscopic examination, made by so competent an histologist as Robin, discovered no lesion of the cord. Such a case as this would certainly show that, although in the majority of cases paralysis may be spinal, it is not always or necessarily so. Indeed the opinion of Leyden, quoted by Dr. Jacobi, that various lesions or morbid processes may underlie the same clinical history, is pertinent in this connection. Three different lesions were found in four autopsies of cases that presented all the clinical history of acute anterior polio-myelitis. Leyden also called attention to the fact that the peripheric nerves have not been studied so thoroughly as the spinal cord. Mr. R. Barwell, in the London *Lancet*, 1872, claimed that infantile paralysis was purely peripheral, involving the ultimate fibrillæ of distribution of the nerves among the muscular elements. According to this author the essential condition consists probably of some subtile derangement in relationship between the ultimate muscular and terminal nerve-fibres, either from an inflammatory or from some chemical or nutrient change. Any degeneration in motor nerve-cells and nerve-fibres that may occur is secondary to the paralysis. While this theory contains a plausible, and possibly a true, explanation of a certain number of cases, it certainly can be ruled out at the present time as a generalization intended to cover all cases. Leyden, in the *Zeitschrift für Klin. Med.*, 1880, advances a more rational explanation, when he considers that in atrophic paralysis there may be a coexistence of neuritis with a spinal-cord lesion, and that instead of such forms of paralysis always originating in the spinal cord, they may have their beginning in any part of the motor apparatus, thence spreading to other parts, or remaining limited to the part first affected. This author does not attempt to deny the common conception of anterior polio-myelitis, but simply insists on the frequent coexistence of neuritis, thus affording a varying point of departure for the morbid process. He claims that where complete recovery takes place, the morbid process has always remained peripheric. Leyden's theory has appeared to the author of this paper to afford a satisfactory explanation of certain cases that have been observed clinically. It is true no autopsies are to be recorded, as such cases have always recovered. In two instances Leyden found the sciatic nerve affected, in one case by an interstitial neuritis, and in another by partial atrophy. Oppenheim has reported a case in which spinal cord lesions and multiple neuritis coexisted in the same individual.[1] In the usual absence of autopsies, particularly in cases that completely recover, from what we now know of the symptomatology and behavior of spinal and peripheral lesions, we are more justified by the clinical evidence in regarding certain cases of paralysis in children as due, at least primarily, to peripheral neuritis than to polio-myelitis.

James B——, aged five and a half years. Father has had rheumatism, but otherwise healthy. The mother died of consumption. The boy has been healthy. His illness began with pains in both ankles and the dorsum of the feet. He would cry when his shoes and stockings were put on. This was followed by a gradual loss of power in both feet and legs. In two weeks the paralysis was pretty complete. After the trouble in the legs had lasted a week, the left wrist began to drop, and four days later the right wrist was affected in like manner. The paralysis became complete in a few days. I saw the boy after he had been ill a little over three weeks, when he had complete drop-foot and wrist-drop. Both parts were likewise extremely painful to the touch. The pain was much aggravated by attempting to extend the feet or move the hands, which actions caused sharp cries. The pain in the legs was most severe along the course of the anterior tibial nerve, and did not appear to extend much above the knee. He was utterly unable to stand, and the effort caused great pain. The paralysis of the extensor muscles of the hands and fingers was likewise complete, as they hung perfectly helpless, unable to grasp a single object. There was some atrophy of the parts. A slow improvement began, and in a week or so the boy could take hold of objects and make some effort to walk, although the latter caused pain. In five weeks after the time I first saw him he could walk fairly well. Pleased at the improvement, his father took him a long walk upon a certain day, with the idea of strengthening his weak limbs. The next morning he cried with pain when he attempted to put on his stockings. He was likewise seized with vomiting, fever, and a recurrence of the

paralysis in the legs, which were painful upon handling. The arms and hands remained the same. Two nights after this he was again taken with vomiting, followed by pains in the arms. The following day, when I saw him, the pains in the arms extended above the elbows, and the drop-wrist was once more complete. Temperature, 99°. He had refused food for two days. I saw him two days later, when he was worse. The child was complaining constantly of pains in the arms and legs, crying out if they were touched. He had vomited all food, but wished to drink constantly. Pulse, 120, and weak; temperature, 98½°. He appeared to doze most of the time, waking up with cries, and presented a pitiable picture of helplessness and misery. There soon began, however, a slow improvement, and in a few weeks he could begin to use his limbs again. I watched the case with interest until leaving town, when the boy was in fair condition. Upon my return I could not find him, so that I cannot report whether he had any further relapses. If so, I think his father would have brought him back to me, as he was very faithful in his attendance. Lead-poisoning was excluded by the absence of lead in the urine and the lack of symptoms. During the treatment he was given ergot, the bromide and iodide of potassium, salicylic acid, and quinine, at various times. The combination of the bromide and iodide of potassium appeared to do more good than the other remedies.

Louisa B——, aged three years. Family history as follows: Father has had nasal catarrh and eczema. He has one cousin that is an idiot, and two that are deaf and dumb. The mother considers herself healthy, but has had one still birth and two miscarriages, one occurring at four months and one at two months. Louisa has never been a healthy child, although there is no distinct account of illness until she was sixteen months old, when she had bronchitis and a sore throat, that was probably diphtheritic, judging from her mother's description. This left her in a delicate condition. When two and a half years old she had an attack of measles, followed by sore eyes. About fifteen days after recovery from the measles she was taken with fever, complained of pains in the legs, and lost power in them. The paresis was very gradual in its onset, not being complete for over two weeks. She would first attempt to walk by steadying herself between chairs, and when the ability to do this was lost, she tried to creep, with the toes turning in. The paralysis of the legs was followed by atrophy. The mother says it pained considerably to touch her anywhere from the hips down. This condition remained for six months, when I saw her in the beginning of August, 1885. Two weeks previously, the child had been taken to Rockaway and given a partial bath, which was followed by pains and paralysis developing rather suddenly in the hands and arms. At the time I examined her there was marked wrist-drop and loss of power in the forearms. The child was badly nourished and fretful. Whenever her arms or legs were touched she would cry with pain. This crying was not aggravated by any distrust of strangers, as it occurred the same when her mother handled the parts. It was impossible to sharply localize this pain on account of the distress produced by the examination and the extreme peevishness of the child. It appeared to be greatest, however, in the hands and feet. There was a loss of faradic reaction in all the muscles of the leg below the knee, and in the extensor muscles of the arm, likewise a reaction of degeneration to the galvanic current. R. Ant. Tib., ACC at 14 cells, CCC at 21 cells; L. Ant. Tib., ACC at 15 cells, CCC at 22 cells; R. Peronei, ACC at 26 cells; Post. Tib., no reaction; R. Extensors of fingers, ACC at 11 cells; CCC at 13 cells; L. Extensors of fingers, ACC at 11 cells; CCC at 13 cells; Flexors of fingers, CCC > ACC. The patella tendon reflex was normal on both sides. The legs were atrophied, likewise the muscles on the back of the arm. The child was not able to stand, crying bitterly when the legs were touched to the floor. She was put on tonics and the iodides, and given applications of electricity. There was a slow improvement, and in several weeks she could use the legs some, and grasp objects with the hands. The general condition also improved. The appearance of the case bore a resemblance to lead palsy, but corroborative symptoms were absent, and an examination of the urine showed no lead. To my surprise, the case went on to a slow but complete recovery. I doubt if treatment had much to do with this result, as she was brought very irregularly to the clinic, and only had electricity a few times. She remained in the same environment during all her illness.

In the following case there appeared to me to be some neuritis present, in addition to a spinal paralysis. J. C——, aged three years, was taken sick suddenly at night with fever, vomiting, and loss of power in both legs and arms. He cried a good deal with pain. He afterward lay quietly when left alone, but if the extremities were touched would utter cries of suffering. There was hyperæsthesia in all parts of the body. Improvement was slow, beginning in the arms. For the first few weeks he was perfectly helpless, being unable to turn in bed without aid. In about six week he sat up in bed, and after this recovery was rapid. Within three months he was quite well. Pain upon touch was the most prominent symptom in addition to the paralysis.

In the above-mentioned cases there was no evidence of spinal meningitis to account for the continuous pain. I could not thoroughly satisfy myself as to the underlying cause of the trouble. The first case had a strongly rheumatic look to me. His father has been subject to this disease, and I think there was an element of it in his case. Salicylic acid did not afford any relief to the paralysis. Dr. Shrady tells me he has lately seen in consultation a girl, four and a half years old, who was attacked five months ago with symptoms regarded by the attending physician as rheumatic. There was severe pain in both lower extremities, but worse in the right. She was in bed for two days with fever, and on attempting to get up the right leg gave way, and she fell to the floor. The pain ceased at the end of ten days, but the paralysis continued, although it is now improving. There has been atrophy and a loss of faradic reaction. There has likewise been a long patch of anæsthesia on the outer part of the right leg.

In the boy's case, while the symptoms showed a multiple neuritis, there may have likewise been some involvement of the spinal cord. Gowers, in discussing "migrating neuritis," states that it may reach the spinal cord and there produce various disturbances, the inflammation either spreading in the tissue outside the dura mater, or extending to the cord, causing subacute or chronic myelitis, with or without meningitis. He thinks the paralyses that occur secondarily to some visceral diseases, as those of the bladder, and commonly regarded as reflex paralysis, are probably produced through the agency of an ascending neuritis.

Malarial poisoning appears able to produce a more or less severe form of multiple neuritis, with resultant paralysis. Gowers reports two cases of paraplegia that were apparently due to malarial neuritis, both being developed in well-known fever districts. Dr. Holt has allowed me to report the following case that came under his observation: A boy, aged thirteen, was first seen November 15th, being taken with chilly sensations, followed by fever, on the 12th. On the 13th he seemed better. On the 14th he got up with severe pains in the left thigh and milder pains in the right thigh. When seen at the dispensary he had a well-marked limp, favoring the right side, and this thigh was extremely hyperæsthetic, particularly along the sciatic nerve. There was likewise tenderness along the left sciatic nerve. Temperature, 99½°. The pain and lameness disappeared in a few days under antimalarial treatment. The case was seen by Dr. Starr, who regarded the trouble as peripheral and of the nature of neuritis, perhaps in a congestive stage.

Probably the trouble would have been of longer duration if the source of irritation had not been recognized, and removed by appropriate treatment. Nothnagel makes the differential distinction between simple neuralgia and neuritis to be the painful points in the former case, and continuous pain in the latter over the course of the nerve.

There are a number of cases of painful paralysis, coming on with malarial fever, that are recorded in the history books of the Hospital for Crippled and Ruptured in this city. With the permission of the hospital I report here two of these cases, as interesting in this connection, although, of course, not venturing an opinion as to the true nature of the trouble. Henry S——, aged five and one-half years. Family history good. They live in a very malarious spot. After suffering for several days with malarial symptoms, one morning he was unable to get up. The limbs were painful; he would cry if they were handled, and could not use them. There was a high fever every night. The child lay on his back, with the lower limbs and feet extended. Complete recovery took place in a month under quinine.

Agnes W——, aged nine, lived at Ravenswood. She had malarial fever, during which she complained of pains in the ankles. After being in bed a week, it was found that her feet were weak and she was unable to stand. About the same time there was paresis of the hands, which were partly dropped. The duration of the paralysis was four and a half months. A gradual recovery is now taking place.

It has seemed to me that cases of paralysis in children, in which pain is a prominent and persistent symptom, where the loss of power has perhaps been gradual and ascending, and where there has been slow but complete recovery, without deformity, after a long interval of time, a careful investigation will generally reveal a peripheral lesion as the cause of the trouble. A possible explanation of pain is that it is due to a marked general congestion of the gray matter of the spinal cord, this congestion taking place in the area of a definite artery. Adamkiewicz has shown in his plates that the anterior spinal artery supplies not only the anterior portion but the whole of the gray matter, principally, with blood, and the presence of pain in certain cases may simply be a question of degree as to the extent of congestion. But the cases that I have reported, and others like them, present no other symptoms showing irritation in the deeper part of the cord. A general congestion or myelitis should cause bladder symptoms, bed-sores, and other disturbances. The continuance and severity of the pain itself do not appear to point to a central cause. Some excellent authorities have considered that unless children with spinal paralysis are speedily cured, perfect recovery will never take place. Leyden appears to consider that if atrophic paralysis eventuates in recovery, the case was multiple neuritis and not polio-myelitis. He considers that regeneration of the ganglionic cells of the cord has not been demonstrated in the same manner as of the peripheric nerves. Gowers states that it is remarkable, in multiple neuritis, how much improvement may take place even after the paralysis has been considerable for a year. The same author, in his recent work, considers there is no doubt that many subacute and chronic cases, which have been described as atrophic spinal paralysis, are peripheral, not central, in their nature, and are cases of multiple neuritis. He considers that the distinction rests on the symmetrical localization of the neuritic palsy, while that of polio-myelitis is characteristically random in distribution; on the persistence and severity of the neuritic pains; on the tenderness of the inflamed nerve-trunks; and on the anæsthesia in the area of their distribution, a symptom never present in polio-myelitis. Paralysis of physiologically related muscles has been regarded as rather pathognomonic of polio-myelitis, but Professor M. Bernhardt states that Eisenlohr has shown that in disease of the peripheral nerve-tracts, functionally related nerve-fibres may be affected, while adjacent fibres remain healthy.[1] The following points may be considered in making a diagnosis:

Peripheral Neuritis.	Polio-myelitis.
Disease usually begins slowly.	Suddenly.
Paralysis progressive. Involves different members, generally in the nature of an ascending palsy.	Paralysis regressive. Involves at the start all the members affected, some parts quickly recovering.
Pain is usually continuous, especially marked upon handling, and involves certain nerves.	Usually no pain. May be general hyperæsthesia at the beginning.
Perfect recovery may take place after the paralysis and atrophy have lasted a long time.	No recovery after the disease has lasted a short time.

This scheme is provisional and not altogether satisfactory, yet it affords points that, taken collectively, will often make a diagnosis possible. It certainly seems desirable to make the effort, when we consider the statement of Gowers that, until recently, all cases of multiple neuritis were looked upon as spinal. I presented before this Society, on a previous occasion, two children, aged five and seven years, who had repeated attacks of paralysis followed by partial recovery. The first seizures were accompanied by pains and soreness of the limbs. The true nature of the trouble was for some time overlooked, but finally lead-poisoning was found to be the cause of the paralysis. I considered the lesion produced by the lead was confined to the spinal cord, but, with later knowledge on the subject, I am inclined to think that the lesion was largely peripheral. The fact that the later attacks were not accompanied by sensory symptoms does not militate strongly against this view. Schultze has reported a case of lead paralysis in which the radial nerves, below the point where the branch to the supinator muscle is given off, were inflamed, the sensory branches of the nerves being slightly, if at all, involved. The spinal cord was normal.[2] Oppenheim has likewise reported a case where microscopical examination revealed inflammation of the peripheral nerves, together with a lesion in the spinal cord.[3] I think that lead may be not seldom at the bottom of obscure paralyses of children, and where recovery takes place after a long interval of time the lesion must be largely peripheral.

It is impossible in the present state of knowledge to accurately define all the causes that can involve the peripheral nerves in children, with resultant pain and paralysis. Cold usually attacks by preference the peripheric system of nerves. The loss of power sometimes following rheumatism is also probably of this nature. Erb states that rheumatic paralysis may arise in all parts of the nerves and in all nerve regions, but, perhaps, attacks the peripheric nerves most frequently. Any morbid blood condition appears able to induce a peripheral paralysis in early life. The group of diseases that Soltmann includes under his hæmatogenous paralysis includes all such conditions.[4] The paralyses following acute infectious diseases, especially diphtheria, are now known to be largely peripheric. Traumatic causes may be present at any period of life.

The object of this paper is intended to be suggestive, not dogmatic. The writer has gladly availed himself of recent studies in peripheral neuritis, as appearing to throw light upon some of the paralyses of children that have caused much perplexity. Assuredly the great differences in the clinical behavior of paralysis in early life, in duration and curability, must admit of different anatomical and pathological explanations.

A New Hospital for Contagious Diseases, having a capacity of four hundred and forty-eight beds, is about to be erected in Milan. In addition to the main building there are to be separate pavilions for small-pox, diphtheria, and typhus fever.

BOVINE TUBERCULOSIS: ITS COMMUNICATION BY INGESTION, INHALATION, AND HEREDITARY TRANSMISSION; ALSO ITS DANGERS TO THE PUBLIC HEALTH.[1]

By M. D. BLAINE, M.D.,

ASSISTANT PHYSICIAN, WILLARD ASYLUM FOR THE INSANE.

In comparing the opinions of our most able writers and experimenters upon this subject, we find a great want of unanimity regarding the question: Is consumption or tuberculosis inherited or acquired, or is it both inherited and acquired?

The general practitioner, in studying this disease, forms his opinions, in most cases, from circumstantial evidence, derived from daily observations of his patient. Oftentimes he feels that many important facts could be obtained if experiments were permissible upon the human subject. His moral convictions restrain him, however, and in order to study the disease thus experimentally he is compelled to resort to the lower animals. The objection is made by some, that whatever the results obtained by experiments on animals, it does not necessarily follow that like results would be produced in the human being. When we consider the fact that the animal possesses nearly the same organs as mankind, which are similar in their anatomical construction, and are governed by the same physiological laws, and that like pathological conditions arise under similar circumstances, why then, if tubercle be found in a new-born calf, should we doubt the possibility of its production in a human subject under like conditions?

As my remarks are confined to the bovine species, I shall take it for granted that the same results may be obtained in the human family.

According to Fleming, the disease is met with whereever cattle are kept in a state of domesticity. It is seen in Russia, Sweden and Norway, Denmark, Germany, Holland, France, Spain, Portugal, Austria, Hungary, Greece, Italy, Algeria, Australia, New Zealand, the Northern United States, Canada, and Mexico. In the latter place, he states that thirty-four per cent. of the animals killed for food are found affected, consequently causing much loss. In all those countries where the animals are stall-fed we find the disease more prevalent. In France and Germany, for instance, the disease has gained such boundless limits that the governments have found it necessary to establish abattoirs. They have also placed the dairies under the inspection of competent veterinarians, in order to protect the public health, which otherwise would have been endangered; and to-day we find that in nearly every country where the disease exists to any extent, they have established the same protection as France and Germany.

I will here give an abstract from Fleming, in which he states, according to the excellent abstracts prepared by Goring on the sanitary condition of animals in Bavaria, that there were in that country in 1877 and 1878, respectively, 4,976 and 5,052 cattle affected with this disease, or in 1877 1.62 per cent., and in 1878 1.61 per cent. In 1,000 bulls, 5.84 were tuberculous; in 1,000 bullocks, 1.39; in 1,000 cows, 2.50; in 1,000 heifers, 0.35; in 1,000 calves, 0.09.

In 1877, of 4,976 cattle recognized as tuberculous, 64, or 1.31 per cent., were less than a year old; 328, or 10.81 per cent., were from one to three years old; 1,846, or 37.80 per cent., were from three to six years old; and 2,445, or 50.07 per cent., were more than six years old.

In 1878, the 5,052 tuberculous cattle were apportioned as follows: 65, or 1.3 per cent., were less than a year old; 551, or 10.2 per cent., from one to three years; 1,730, or 34.5 per cent., from three to six years; 2,360, or 46.5 per cent., more than six years. For 336 animals the age was not noted.

Goring, in publishing this abstract, remarks that the veterinary surgeons are not always informed as to the existence of the disease, and that the numbers given above must be considerably below the actual amount in any case.

Adam, in investigating the list of animals killed in the abattoir of Augsburg, arrived at the following results: In 1879, of 10,988 cattle slaughtered, 321, or 2.92 per cent., were tuberculous; in 1880, of 11,688 slaughtered, 262, or 2.24 per cent.; in 1881, of 12,500 slaughtered, 247, or 2.00 per cent.

According to Drexler, of 55,882 cattle slaughtered at Munich in 1875, 704, or 1.25 per cent., were affected with tuberculosis in a very evident manner. Trapp reports that among 11,079 cattle killed in the Strasburg abattoir in 1880, 220, or 1.9 per cent., were tuberculous (this number did not include those slightly affected). For the same year Mandel found 174, or 3.4 per cent., among 5,105 cattle slaughtered in the Mulhouse abattoir; and in 1879 Strobl and Magin recorded 1,125, or 2.5 per cent., of 44,699 slaughtered at Munich.

As regards the ages of the animals, the 1,125 were classed as follows: Cattle under one year, 2, or 0.2 per cent.; from one to three years, 81, or 7.1 per cent.; from three to six years, 378, or 33.5 per cent.; over six years, 664, or 59.2 per cent.

The 1,125 tuberculous cattle may also be apportioned in the following order: 218, or 1.13 per cent., of 19,284 bullocks slaughtered; 558, or 5.30 per cent., of 15,789 cows; 40, or 0.68 per cent., of 5,823 bulls; 28, or 0.73 per cent., of 3,803 heifers; 1, or 0.0006 per cent., of 149,971 calves.

From these figures it results that: About two per cent. of the cattle sent to the abattoirs of these different towns are affected with tuberculosis; the proportion of male to female animals so affected is as one to three; the greatest number of animals are over six years of age; after these, the greater number is from three to six years; very young animals are almost exempt from tuberculosis.

Thus I might continue to quote statistics for hours, but in the end they only tend to establish the necessity of having abattoirs in every country where the disease exists in any degree.

In this country we have no abattoirs, neither have we any compiled statistics relative to the frequency of the disease. The only authentic report that I have been able to find is that made by Professor Law, of Cornell University, and this report refers to a locality and not to the general prevalence of the disease. In his report to the Department of Agriculture, of the contagious diseases of our domestic animals, he says that "twenty, thirty, and even fifty per cent. of certain herds, that supply New York City with milk, are affected with this disease. In some country districts can be shown large herds with ninety per cent. subjects of tuberculosis."

During the past two and one-half years I have examined over four thousand head of animals in different sections of this State, and I find that the disease is more prevalent than is generally known. The majority of animals that I have examined were milch-cows, and I found twenty-one per cent. manifesting symptoms of the disease; but perhaps not over four per cent. of them manifested pulmonary lesions. I have visited some herds where at least fifty per cent. could be shown to be tuberculous. The disease seems to be much more prevalent in some localities than in others. For instance, in low, wet, and marshy districts it is very common; also in places where animals are poorly fed and kept in close confinement, and in poorly ventilated stables.

I visited your stock-yards during the month of July last; also examined a number of herds about your city and Brooklyn. The morning I visited the stock-yards at 159th Street, in company with Mr. Romane, one of your meat inspectors, I saw thirteen cows that were offered for sale, three of which were badly diseased, and one of the three was a cow thirteen years old, and mani-

[1] Read before the Section on Hygiene and Public Health, New York Academy of Medicine.

fested pulmonary lesion. I acquainted Mr. Romane of the fact, and when he consulted the manager of the yard in regard to the cattle, he said that they had been sold to parties in Jersey City for milkers. I visited herds that furnished milk for the city of Brooklyn, and I did not fail to find tuberculous animals in every herd that I visited, and in some herds to a great degree. But I was astonished in not finding more disease than I did, as the manner in which the animals were being cared for was not only unhygienic, but cruel, especially in winter, as several herdsmen informed me that their animals were tied in those small barns in the fall, and were not taken out in the open air until spring time.

Occasionally we read in our daily papers of sudden outbreaks of the disease in different parts of our country, where whole herds are destroyed, as was the case at the Willard Asylum, Willard, N. Y.; the asylum sustaining a loss of nearly two hundred head. I believe, if all the reports throughout our country could be gathered together, we would find that the disease has already developed to an alarming degree.

I now wish to call your attention to certain clinical observations that were made by myself of the herds at the Willard Asylum, extending over a period of two and one-half years. During the fall of 1883 tuberculosis broke out in an acute form in the asylum herd, which consisted of about one hundred head of milch-cows and forty head of young stock, most of which were of Holstein blood, and with the exception of a few head, all were in excellent condition and thought to be in perfect health. During the summer months, however, a number of the cows were noticed coughing, which attracted some attention, but nothing of a serious nature was suspected until late in the fall, when those that had been noticed coughing began to emaciate, presenting in general a very bad appearance; the hair seemed dead, having lost its gloss, standing erect, cleaving from the skin. Their eyes were sunken and presented a heavy appearance. The animals did not move about, and usually lingered behind on going to and from pasture, and if hurried, they seemed exhausted from want of breath. My attention was called to them, and on examination I found in several cases an entire absence of respiratory murmur over the greater portion of either lung, and where the respiratory murmur was perceptible I detected moist râles, and in places the râles had assumed a resonant character, which indicated consolidation. A severe diarrhœa had now developed, which was very offensive, and the milk-supply had gradually lessened for several months. Finally, it was thought best to kill one of the feebler ones, and ascertain the true nature of the disease.

Case I. The animal chosen for examination was eight years old, of Holstein blood, and one year previously would have weighed 1,200 pounds. On post-mortem, the animal was found highly tuberculous, and there seemed to be no organ in the body free from the disease. The lungs were voluminous and double their normal weight. They were completely adherent on either side, and the left lung on section seemed to be one mass of tubercular deposit. Small vomica had formed in some places, in other places the deposit was calcified, and in still others, cheesy. The bronchial glands were three to four times their normal size and degenerated. Numerous tubercles the size of hazel-nuts and smaller, were found upon either surface of the diaphragm, and the liver was found at least three times its normal size and contained large masses that would equal in weight several pounds. On cross-section it revealed large cavities filled with a muco-purulent mass. The bowels were covered with tubercles, and in a state of subacute inflammation. All of the abdominal organs were more or less affected, also the milk-bag, which contained several large deposits, some of which were calcified, and others softened and in a semi-purulent state. All of the glands throughout the body were enlarged, and in places degenerated.

Case II. was that of a Holstein six years old, much emaciated, and suffering from a chronic diarrhœa. No respiratory murmur was heard over the right side of chest-wall except at the apex. General enlargement of the superficial lymphatic glands, also of the sub-maxillary and thyroid. Post-mortem examination: Lungs completely adherent on either side, and differing in no respect from those in Case No. I. The lungs, with the heart and deposit intact, were removed and weighed, which weight equalled thirty-nine and one-half pounds. Deducting the weight of the normal lung and heart intact, we find about twenty-four pounds of tubercular deposit. The liver was double its normal size, and on section large quantities of muco-purulent fluid escaped; the mesenteric-glands were degenerated, and the bowels were completely studded with tubercles about the size of peas. The milk-bag contained one large deposit between its two lobes which was calcified. The finding of these two animals so badly diseased, there being others that were failing and manifesting similar symptoms, naturally created a great amount of anxiety on the part of the medical superintendent, Dr. Chapin, who requested that I make an examination of the whole herd. On making such examination, twenty-four were found manifesting symptoms of the disease, besides several that were considered questionable. Finding so many diseased, they being the property of the State, it was thought best to seek advice from one of our State veterinarians, as to what means were best to adopt. Professor Law, of Cornell University, was sent for. After making careful examinations of the herd, he reported that twenty-six were diseased, and that he considered several suspicious, as they manifested some symptoms of the disease, although he was unable to detect anything abnormal on auscultation. He advised the killing of all those that were diseased, the isolation of those that were considered doubtful, and a thorough disinfection of the stables. Having in the herd a full-blooded Holstein bull, it was considered quite essential to know if he was affected, although he had not manifested any symptoms of the disease. Upon careful examination nothing abnormal was detected. Professor Law's examinations were made March 22, 1884.

Many of the diseased animals remained in the herd for several weeks, when the herd was again examined by myself. I found that those that only a few weeks previous were considered doubtful, had now developed positive symptoms of the disease, and still others were found that seemed quite suspicious. The bull, at this time, appeared to be failing in flesh, but manifested no positive symptoms.

On May 22d and 23d, twenty-eight of the most advanced cases were killed. On examination all were found affected, but not all to the same degree. The organs principally affected were the serous membranes, the lungs, liver, bowels, and the milk-bag in many cases. A number of them were affected to an equally great degree as the two cases I have already reported. Examination was again made of the herd on June 10th, and others were found manifesting the usual symptoms; the bull was again examined and it was very apparent that he was affected, although he had not manifested any cough, but he was rapidly losing flesh. He was then weighed, and was found to weigh 2,456 pounds. He was again weighed on July 10th, and his weight was then 2,290 pounds; and as at this time it was very evident that he also was affected, it was decided to kill him. On post-mortem we found a large deposit in the central portion of the left lung, and numerous small tubercles upon the left pleura. The bronchial glands were greatly enlarged, and on cross-section were found calcified. There were many tubercles upon the peritoneum and bowels. The liver in this case seemed free from disease. Upon the glans penis were several small tubercles, and in one place it appeared as though several had coalesced and had broken down, leaving a cicatrix. Had this been ulcerated, one might have thought it a soft chancre.

Leaving the herd at present, I wish to call your atten-

tion to the calves that were born during the winter and spring of 1883–84. Writers tell us that it is not an unusual occurrence for animals well advanced in tuberculosis to abort. This seems to be true, as such was the case in this herd. I observed that eight calves were prematurely born, two of which required assistance at birth, as the mothers were much exhausted. One of the two that were removed was in about the eighth month of gestation. This fœtus on examination was found saturated with tubercles, some of which were as large as peas, and on drawing a knife across them they were found calcified. Tubercles were found in the liver, bowels, diaphragm, and chest-wall; there being none observed upon the lungs. The mother of this calf was killed some weeks afterward, and was found highly tuberculous, the disease being well advanced to the third stage, or stage of suppuration.

No. 2 was from a diseased mother, also in about the eighth month of gestation. On examination I found the liver, diaphragm, and bowels quite thickly studded, but the tubercles were much smaller than in the preceding case. Of the other six prematurely born, I was able to examine only two of them, as the other four had been destroyed before I was acquainted of the fact. One of the two, however, that I did examine, was found to have a tuberculous liver.

During the winters and springs of 1883–84 and 1884–85 fifty-three calves were born to the herd, and each one was examined with reference to the disease. Twenty-nine of the number were found tuberculous in some of the viscera. The greater number of the calves were killed within five weeks after birth, and the whole number before the expiration of four months. I will only call your attention to the most interesting cases. One calf killed at the age of five weeks was found highly tuberculous. The liver was double the normal size and covered with tubercles. On cross-section it was found to contain a large vomica, filled with at least one pint of fluid of a muco-purulent character. Tubercles were also found upon the pleural surface of the left lung; also an extensive deposit in the apex of the same lung. The mesenteric glands were enlarged and cheesy. The bowels were thickly studded and in a state of subacute inflammation. This calf had suffered from a severe diarrhœa for several days, and had failed considerably in flesh.

The mother of this calf was killed shortly afterward, and was found badly diseased. Among the organs affected was the milk-bag, which contained a large tuberculous abscess. In this case does it seem possible for the disease to have been acquired wholly after birth? To my mind it does not seem possible that the disease could have developed with sufficient rapidity to have produced an abscess of the liver in such a limited time. However, I am of the opinion that the intestinal lesions were produced, to a great extent, from the milk of its mother, as undoubtedly the milk must have contained elements of the disease.

In another calf, seven weeks old, the left lung was adherent to the chest-wall at the apex, where there was a large tubercular deposit. Also there were many small tubercles upon the lungs and in other places. The liver and bowels contained many tubercles the size of peas, and on cross-section were found in a state of cheesy degeneration. In the remaining cases the lesions were not as marked, but the disease was none the less apparent.

You have now the history of the herd up to June, 1884, and we find that nearly one-half of the herd of milch-cows has been disposed of, all that were supposed to be diseased having been killed. The remainder of the herd were observed from time to time, and examinations repeated every twenty to thirty days; and upon each examination new cases were discovered, which were immediately removed from the herd, as it was thought they could be fattened and made use of.

The sorting out and feeding continued for several months, and at the time of killing many had not gained at all, while others had taken on considerable flesh; but upon killing only five were found fit for use, and four of these were slightly diseased in some of the viscera.

During the spring of 1885 a number of young heifers, which had been kept upon another portion of the farm, were with calf by the bull killed in June previously. Before putting them with the old herd they were examined, and many of them were found diseased. It was deemed advisable to kill them. The calves of these heifers were all diseased, the disease in one calf being traced directly to the bull, as the mother was found unquestionably healthy. The remainder of the young herd which had been exposed to the disease were put with the remaining portion of the milch-cows, and the combined herds now numbered about forty head. The examinations were still continued from time to time, during the summer and fall of 1885, and occasionally one was found manifesting the usual symptoms of the disease. This procedure was continued until the spring of 1886, when it was thought advisable to feed the remainder of the herd. During the past summer, all were killed except ten, which have been killed during the past month, and in nearly every case disease could be found in some of the viscera, and some badly diseased, as I will show you from specimens that I have here. The specimen that I wish to show you is a very interesting one, inasmuch as it shows that one is not able, at all times, to tell whether or not the animal is diseased. You will observe that the disease, in this case, is confined wholly to the bronchial glands, there being no other organs affected—that is, as far as I have been able to determine. Auscultation of the lungs in this case revealed nothing abnormal, and the superficial lymphatic glands were not enlarged, and the animal had not manifested a cough. The bronchial gland, in a healthy cow, is about four or five inches long, about one inch wide, and one-half inch in thickness. Here we have a specimen, removed from a Holstein cow nine years old, in which we find the gland is about ten to twelve inches in length and nearly six inches in thickness. This, on section, we shall find in some places calcified, and in others cheesy. I also have other specimens here, removed from another case, in which no disease could be found except in the glands, and these without apparent enlargement.

During the winter of 1883 the asylum purchased a full-blooded, registered, Holstein bull-calf, from one of the leading breeding firms of this country. This bull was kept from the herd until old enough for breeding purposes, and then only came in contact with the herd as occasion required. This animal thrived until April last, when I noticed that he began to manifest symptoms of the disease. He was examined at frequent intervals during the summer, and each examination confirmed the previous diagnosis. He was killed on November 16th, last. Previous to being killed he weighed nearly two thousand pounds. On post-mortem I found the left submaxillary gland enlarged and suppurating, the thyroid gland enlarged and calcified, and several deposits in the left lung about the size of walnuts; also tubercles upon the peritoneum and bowels. The liver, in this case, was free from disease. The glands and portions of the lungs I have here for your inspection.

The only possible objection that could be raised regarding the care of these animals was that of ventilation. The stables were kept scrupulously clean, being washed out daily, and there were no cesspools about the barns or yards. The barns are situated upon a side-hill, thus affording the best possible drainage.

Their food was of the best of hay, corn fodder, bran, and vegetables. In the spring of 1884 all of the animals were removed from the barns and put in pasture, and open sheds built for their protection.

During the following winter the animals were con-

fined in the barns only during the time of feeding and milking, they being out during the day and protected at night by sheds open on one side.

Also in the breeding of this herd of stock there was the greatest amount of vigilance exercised in order to avoid inbreeding. Frequent changes were made in the bulls; new cows were bought from time to time of the farmers throughout the country, and these crossed with the Holstein bulls, and at the time of the outbreak of the disease about one-third were animals that had been purchased. In my mind it does not seem possible that the disease, or dyscrasia, had been inherited in all cases. Therefore, if the disease was not inherited in all cases, it must necessarily have been acquired; and if acquired, through what channels did the disease enter the animals' system?

There appear to be only two channels in which it could have entered, the one by inhalation, the other by ingestion. In order to prove that the disease is communicated by inhalation, we have to resort to experiments, but by ingestion we have many striking examples in which it is plainly shown that the disease is acquired by the use of milk and meat of tuberculous animals. In proof that the disease may be acquired by the ingestion of tuberculous substances, allow me to call your attention to the asylum herd of swine, which numbered nearly three hundred head. These animals were kept in different yards. In one the breeding sows; in another, the half-grown pigs, and in the third yard, which was adjoining the slaughter-house, were kept the large hogs which were being fattened. The hogs in this latter pen had access to the offal from the slaughter-house, where a number of tuberculous cows had been killed. Later in the fall a number of the large fat hogs died suddenly in full strength, and on post-mortem were found highly tuberculous. The disease, however, did not present the same pathological conditions as in the cows. The disease seemed more especially confined to the abdominal viscera and the glandular system, the lungs being rarely affected. In those cases that died suddenly I found a tubercular peritonitis, to which was attributed the cause of death. During the killing season many were found diseased, there being large metastatic abscesses in different portions of the body, but more especially in the side; and in the sows the rudiments of the milk-bag were often the seat of abscess. Also the joints were frequently affected, many of the hogs, both large and small, became lame. During the winter a number of them became partially paralyzed in their hind parts. The paralysis progressed, and finally they were unable to use their hind limbs at all, and for several days three of them moved about, walking upon their fore limbs and dragging their hind parts. Still they were fat and seemed to eat equally as well as the others. Finally they were killed, and on post-mortem the bodies of the vertebræ in different portions of the column were found to have undergone caseous transformation. The cord at these points was softened, and in some cases completely obliterated.

There were three sows in this yard that proved to be with pig. They were taken out and put with others in another yard. One of these sows, shortly after pigging, became paralyzed similarly to those that I have already alluded to. In about three months her young pigs became hollow-backed; they walked about with their bellies touching the ground. Finally they were killed. All were found diseased, and the bodies of the vertebræ very incompletely formed. The other two sows became paralyzed and were killed before pigging, but unfortunately an autopsy was not held.

After the killing of all the swine that had access to the offal, and disinfecting the yards, we have since had no more disease in the herd.

In searching the literature on the feeding of tuberculous substances and meats of tuberculous animals, we find that the disease is often transmitted by the use of such products. We find in the work by Herr A. Lydtin, G. Fleming, and M. Van Hertsen the following:

Animals experimented upon.	Affirmative. Per cent.	Negative. Per cent.	Doubtful. Per cent.
1 horse	0.0	100.0	0.0
5 calves	100.0	0.0	0.0
35 sheep	51.4	42.9	5.7
13 goats	84.6	15.4	0.0
60 pigs	65.0	18.3	16.6
17 rabbits	31.2	66.5	2.3
20 dogs	25.0	75.0	0.0
9 cats	55.5	44.4	0.0
6 guinea-pigs	83.3	16.6	0.0
2 pigeons	0.0	100.0	0.0

Of 322 alimentation experiments 259 were made with uncooked food; and of these the affirmative results were 47.7 per cent., the negative results 48.9 per cent., and the doubtful results 3.3 per cent. In 62 experiments aliment was employed which had been cooked for ten or fifteen minutes, and the following were the results: 35.5 per cent. affirmative, 64.5 per cent. negative, and 1 per cent. doubtful.

Classification of these experiments according to the alimentary substances employed gives the following results:

	Affirmative. Per cent.	Negative. Per cent.	Doubtful. Per cent.
117 animals fed with tuberculous matter from heifer	61.5	34.2	4.3
46 fed with the raw flesh of tuberculous cows	13.1	86.9	0.0
91 fed with milk from tuberculous cows	30.7	59.3	1.0
1 fed with milk from tuberculous rabbits	100.0	0.0	0.0
25 fed with tuberculous matter from human beings	36.0	64.0	0.0
33 fed with tuberculous matter from a pig	53.0	47.0	0.0
2 fed with tuberculous matter from a sheep	100.0	0.0	0.0
2 fed with tuberculous matter from a rabbit	50.0	50.0	0.0
3 fed with tuberculous matter from monkeys	100.0	0.0	0.0
5 fed with tuberculous matter from birds	100.0	0.0	0.0

In reviewing these experiments and well-established clinical facts Johne arrives at the following conclusions:

1. The transmission of tuberculosis may be effected from animal to animal, and from man to animals, by the ingestion of tuberculous matters; but this mode of transmission is much more uncertain than that by inoculation.

2. The matters which most certainly transmit tuberculosis by gastro-intestinal ingestion are those obtained from the lungs, the pleura, and the lymphatic glands; the milk of tuberculous animals, with regard to its more or less certain action as contagious matter, coming next to these. Infection takes place less readily with tuberculous matter obtained from mankind than with that from animals.

3. Infection takes place less readily by the ingestion of flesh than by means of substances mentioned in 2; and yet it was employed successfully in seventy-six of the cases shown in the above table.

4. Calves, sheep, goats, and pigs present, as has been already mentioned, and as has been so well shown by Bollinger, the greatest receptivity for tubercular contagium. With regard to the supposed immunity of carnivora, it is not so definite as some authorities believe.

Among experiments which especially merit our attention we mention those made by Gerlach. Of 46 different animals submitted to experiment and fed with uncooked tuberculous substances 35 were infected; of 35 animals fed with uncooked flesh from tuberculous cows 8 contracted tuberculosis; and of 15 fed on cooked tuberculous matter 10 became diseased.

Besides the experiments of Gerlach we may cite those made by Bollinger. The learned experimentalist employed the milk of tuberculous cows, which he gave to pigs, and the conclusions to which his experiments led him, in the presence of pathological preparations de-

rived from them, was that "the prolonged consumption of the milk of tuberculous cows produces miliary tuberculosis in the pig."

I fed thirteen rabbits with uncooked tubercular matter, and at the expiration of fifty-four days found all the rabbits diseased, and to a great degree; the bowels being the principal seat of the affection.

Much has been written during the past few years in regard to the dangers that are attendant upon the use of the milk of tuberculous cows, and many experiments have been performed with a view of determining if such milk is truly infectious. There are many experiments recorded that positively prove that the milk of tuberculous animals will convey the disease to young animals when fed upon it for any great length of time.

The following is from Billings' work on relation of animal diseases to the public health, in which he states that the following were experiments performed by Gerlach, and that the experiments were performed with the utmost care:

"Having a cow afflicted with tuberculosis that still gave milk, it was resolved to use the same to test the question 'whether the milk from such a cow was capable of producing a similar disease in young animals when fed upon it.'

"The cow was seven or eight years old, much emaciated, respiration difficult, and had a rough, weak cough; vesicular respiration perceptible over all parts of the thorax which enclose the lungs, but numerous, unnatural, especially dry, râles were perceptible. In no place was the concussion deadened. No fever. Appetite good. Daily milk quantum, 1,500 grammes. After the lapse of three months the cow was killed. The emaciated condition had gradually increased, and the milk-secretion likewise decreased; in the first month the yield of milk decreased 600 grammes; in the second, 500 grammes, and during the last eight days the secretion ceased entirely, although the animal received all the nourishment she could consume.

"*Autopsy:* The inner thoracic walls, the diaphragm, and the mediastinum were covered with numerous tubercles of variable dimensions; the pulmonary pleura, or covering of the lungs, was far less complicated. The lungs were voluminous and double their normal weight. Nodules and tubercles were distinctly perceptible on palpation. The bronchial lymph-glands were hypertrophied—enlarged—hard and nodulated. Cross-sections of the pulmonary tissues revealed the presence of numerous tubercles and tuberculous devastations; large and small cavities filled with muco-purulent mass, others with caseous material; numerous miliary tubercles were dispersed over the pulmonary tissue.

"With the milk from this cow were fed two calves, two pigs, one sheep, and two rabbits. The first calf died from an accidentally acquired disease.

"Calf No. 2.—A healthy, well-nourished calf, eight days old, was fed with milk from the above-mentioned cow for a period extending over one and two-thirds month; at first it received 1,000, and later 300, grammes of milk daily, an average of about 600 per day; in fifty days the whole quantity of milk consumed amounted to from thirty to thirty-two kilogrammes. Aside from this the calf received other milk; later, diluted milk and oatmeal. Neither phenomena indicated the presence of disease, nor were disturbances of nutritive functions observable. The calf was killed one hundred days from the time that the experimental feeding began, and fifty days after the feeding with milk from the tuberculous cow had ceased.

"*Autopsy:* The pleura of the sharp edges of the right lung was covered with delicate red, filamentous excrescences, which extended as a fringe about a centimetre beyond the edge of the lung. Here and there this neoplastic production formed a connecting membrane in which were to be seen miliary tubercles, as refracting points. The costal pleura, the inner lining of the ribs, was also irregularly covered with a membrane of similar character. In the lungs were to be seen tubercles, otherwise the parenchyma was normal; immediately under the pleura were four small and six miliary tubercles, and more were to be seen in the loose interlobular tissue. The smaller tubercles were more transparent, and had a grayish color, having a firm organic character; in the centre of one of the larger ones was to be seen caseous material. The bronchial lymph-glands were much enlarged; inwardly disturbed by many purulent and caseous centres; here and there lime-salts were perceptible; the tubercle centres extending prominently above the cut surface of the gland. The mesenteric and other glands presented a similar character.

"The microscopical examinations of the tubercles gave the same characteristics as those of man."

"These and more recent experiments prove that the milk from cows affected with tuberculosis is not only harmful, but that it also contains elements of a specifically dangerous character; it is capable of generating elements of a similar character; it, therefore, bears the character termed infectious."

There are many other experiments that are recorded, which tend to show that the milk of such animals is exceedingly dangerous, but I think that it will not be necessary to give you more of them, as they all result in about the same conclusion.

I fed six rabbits with the milk from a tuberculous cow for ten days, and at the expiration of sixty days from the time the feeding was begun no disease was found, but upon killing the cow from which the milk was obtained, I found no lesions in the milk-bag, but extensive deposits in the lungs. I was then led to believe that it was necessary to have a tubercular lesion of the milk-bag or along the lacteal track, thereby allowing the germs to enter into the milk flow. We find that many experiments have been performed with like negative results, consequently many experimenters are disinclined to believe that there is any danger in the consumption of such milk. I observed that in the latter stages of the disease the milk is greatly reduced in its fat elements; the specific gravity in many cases reaching as high as 110 to 115, and the milk bluish and watery in appearance. This fact alone would be evidence sufficient to condemn its use, especially in our children and babes.

It is generally conceded that if tuberculous meats and milk are well cooked previous to usage, there is much less liability of their producing harmful effects.

This calls to my mind a new preparation that has just been introduced into the market, called "Bovinine," the manufacturers of which call special attention to the fact that the blood and the meat of which this preparation is made is rendered into a liquid state without the application of heat. I do not wish to make any reflection upon this preparation, but it does seem as if the greatest amount of care should be exercised in the selection of animals for such purposes.

It is claimed by many that the inhalation of non-tubercular substances, as well as the inhalation of tubercular matter, will produce tuberculosis. In the latter case I can conceive that if tuberculosis is a germ-disease, it can be readily produced by placing the living germ upon fertile soil. In this case it would be in accordance with the laws of reproduction. But when we employ such substances as lamp-black, coal dust, etc., what can be the result other than a local inflammation? I will admit that these substances may become encysted, but I am yet to be convinced that a specific disease may be produced by the inhalation of a non-specific substance.

According to "Sattler-Gunther and Harms, who tried the experiment of causing rabbits to inhale the air expired by tuberculous cows, the results were negative. Later Tappeiner and Lippl added to the air inhaled particles of tuberculous sputa. In all these experiments the animals experimented upon (dogs) developed nodules in the lungs only in some cases, in others in several organs at the same time." In looking over the various experi-

ments we find that wherever tubercular matter has been used for inhalation, the disease is usually produced.

I experimented upon seven rabbits in the following manner, putting them into a tight-woven sack and holding the free end over the nostrils of a consumptive cow. This experiment was repeated seven times, at intervals of five days each. Each time, on taking the rabbits out of the sack, they seemed much exhausted. Forty-five days from the last inhalation they were examined, but all appeared healthy. As such experiments have invariably failed to produce the disease, I am convinced that the germ is not given off in the expired air.

I also performed a very interesting experiment in the following manner: Taking some fresh tubercular matter, rendering it into a solution by adding warm water, I applied several drops of the solution to the mucous membrane of the nostrils of seven rabbits, being careful to hold the rabbit's head up so as to allow the fluid to gravitate and reach the bronchi, if possible. I also tried the same experiment with seven other rabbits, but using fresh sputa from one of my patients in the wards of the asylum. Thirty-seven days after I killed those that had been subjected to the human sputa, and found evidence of the disease in four cases, but to a greater degree in some than in others.

No. 1. Left lung, the lower two-thirds solid in deposit, and a large deposit in the central portion of the right lung. Upon the left side lung adhered to chest-wall, and numerous miliary tubercles upon the pleural surface of both lungs, and several tubercles on the liver, three of which were as large as peas.

No. 2. Left lung contained quite an extensive deposit in the central portion. Several small tubercles upon the liver and bowels. In the other two there were miliary tubercles upon the pleural surface of both lungs, with small deposits in the lower lobe of the left lung of each. The other three were found manifesting no lesion of disease.

The seven that had been subjected to the application of the bovine tuberculous matter were examined upon the thirty-eighth day after the application.

No. 1. Left lung contained an extensive deposit in the central portion, and a small deposit in the lower lobe of the right lung. Numerous miliary tubercles upon the liver and bowels.

No. 2. Deposit in the central portion of the right lung; several tubercles upon the bowels, none being observed upon the liver.

No. 3. No deposit in either lung, but two quite large tubercles upon the diaphragm, and several upon the liver and bowels.

No. 4. Right lung, lower half filled with small miliary tubercles. Other organs appearing normal.

Nos. 5, 6, and 7 manifested no pulmonary lesions. The liver contained several small granulations, but I was not positive as to their being tubercular. The pathological appearances in each class were very similar, and one could not have told but that the lesions had all been produced from the same substance. The sputa and tubercular matters employed in each case were fresh, and only one application was made.

Before giving you the ætological conclusion to this paper, let us consider the sanitary measures that are being exercised in this country, especially in our large cities.

In your city, I am informed that you have about forty-five slaughter-houses, ten large markets, and about two thousand two hundred shops, and that there are about twenty-five thousand head of cows that furnish milk to your city. In July, when I visited your city, I was informed that you had one meat inspector and three milk inspectors, and that no animals were examined previous to being killed. May I ask how much consumed in this city receives inspection? Another important question is: What per cent. of the milk consumed is inspected, and what value can there be attached to the inspection of milk after it has left the hands of the producer, other than to guard against adulterations? I contend that the proper place for the inspection of milk is at the producers' stables, and that the animals from which the milk is obtained should be inspected. I do not believe that too much stress can be put upon this point. On the one hand, if we buy milk that has been adulterated or watered we are swindled. On the other, if we buy milk unadulterated, but from an infectious source, it is our health that is in danger. Now, if there are 25,000 head of cattle that furnish milk to your city, and if two per cent. of that number produce infectious milk, you can imagine the dangers to which your people are subjected.

From my observations of tuberculosis I have formed the following ætological conclusions:

1. In the bovine species, the disease is inherited either from male or female.

2. Tuberculosis is acquired by the inhalation of tuberculous substances.

3. Tuberculosis is acquired by the ingestion of milk of tuberculous cows, when the disease has reached the stage of suppuration, or when there is a tuberculous affection of the milk-bag.

4. The disease may also be acquired by the ingestion of the flesh of tuberculous animals.

THE INFLATED RING IN THE TREATMENT OF ECTROPION WITH CATARRH OF THE CERVIX, STUBBORN RETROFLEXIONS OF THE UTERUS, AND PROLAPSE OF THE OVARIES AND TUBES.

By SARA E. POST, M.D.,

PHYSICIAN TO THE OUT-DEPARTMENT OF THE N. Y. INFIRMARY FOR WOMEN AND CHILDREN, ALSO PHYSICIAN TO THE DEMILT DISPENSARY EVENING CLASS FOR WOMEN, NEW YORK.

PROLAPSED OVARIES.

PROLAPSED and hyperæmic ovaries require, in the order of their importance, first, support; second, the prolonged hot douche; and third, possibly, counter-irritation and galvanism. My previous method of obtaining support had been by cotton pads carried up behind the cervix, with the patient in the Sims position. These pads required renewal at least every other day. They were not apt to retain their position longer, and if kept in place longer would become foul. When the pad was removed the vagina required washing out, and it followed that the patient had to make the journey to her doctor's office without her support, or it had to be applied at her own home. Further, when the best had been done the use of the hot douche was still seriously interfered with. It could be given only every other day, when the pad was removed; so that in many cases it was found desirable that the patient with this condition should remain in bed for a number of weeks, in order that she might have the benefit of the frequent douche without suffering from the absence of her pad. The treatment, then, resolved itself into a programme of from four to six weeks in bed, followed by pads to be frequently renewed, preferably at the patient's house; and it resulted that only hospital paupers or the very rich could be successfully treated for this distressing disease. It will not, perhaps, be considered superfluous if I detail a few cases in which rest was impossible, and in which the inflated ring has given relief after other methods at my command had been ineffectually used.

CASE I. was twenty-four years of age, married four years, one child three years previously, no pregnancy since. She came to the infirmary clinic in November, 1885, complaining of constant aching in both inguinal regions. Each step aggravated her distress, and intercourse caused agonizing pain. Dysmenorrhœa was present, the flow lasting for six or seven days and recurring at intervals of not more than two weeks. This patient had been under treatment during the greater

part of the three years, and she had had several consultations over her case. One physician had advised the removal of her ovaries, and another, equally distinguished, had recommended letting them alone, telling her to have patience, that at the age of fifty or thereabouts her pains would be spontaneously relieved. Excluding the chances of oöphorectomy, her case was a sad one. The woman was extremely melancholy, and in relating these circumstances, naively added, "I shall be relieved when I am fifty, but I am now only twenty-five years old." Examination showed the cervix fissured upon the left side, lips everted, cervical catarrh, retroflexion of the uterus, and prolapsus of both ovaries, which were exquisitely sensitive; also a prolapsed and swollen left tube. This patient was treated with the posterior pad, applied twice a week, and in December she reported that she no longer had pain upon intercourse; that she was comfortable so long as the pad was in position; but that when it was out all of her pains would return. Upon examination the ovaries were found still very low, but not so sensitive as upon the first occasion.

In spite of douches and local medication, however, the hyperæmia and catarrh of the cervix continued. At this date an air-pessary was inserted. The patient removed it twice a day for a long hot douche and left it out altogether at night. After wearing it for a couple of weeks the eversion of the lips was found reduced and the discharge had ceased. In February menstruation had become regular. It lasted but three days and was without pain. The patient felt perfectly well, unless she attempted to run the sewing-machine, when some of her old symptoms would return. In March, examination showed the ovaries beyond reach. The tube was still discernible, but there was no discharge, and the pelvic sensitiveness was gone. June 1st, trachelorrhaphy was performed. The cervix was anæmic from the pressure of the ring, and the bleeding was slight. Good union was obtained, and at the date of writing, October 1st, the patient still feels perfectly sound. She remains sterile, but menstruates normally, and examination shows the fundus still forward, and the ovaries above the brim. She has worn no support since the operation, a period of four months. This result is exceptionally good, probably for the reason that the woman was young and that the dislocation had not existed longer than three years.

Case II. occurred in private practice. She was forty-two years of age, had had three children, the last seven years previously. This patient menstruated regularly, the flow lasting one week, and she felt better when menstruating than at other times. Half-way between the periods she had great distress—suffering with sick headaches, transient blindness, and spots before the eyes. She had constantly a profuse leucorrhœal discharge and inguinal pain. She had the ovarian cast of countenance, and was extremely depressed and melancholy. Although surrounded by friends, she would shut herself away and cry by the hour, without attempting to define the cause. She often contemplated self-destruction, being haunted by the fear of a suicidal act. This patient stated that her symptoms dated from the birth of her first child, but that, from the establishment of puberty until becoming pregnant, she had always been "unwell," that she had always worn a napkin, and that the flow was often so profuse as to soak through her clothing and to stain the chair upon which she sat. She was married at sixteen, and her first child was born twelve years later. Whatever construction be put upon the history of these hemorrhages, it is evident that she was not well during the period; while after the birth of this child she was almost constantly under a doctor's care. Examination showed a slight rupture of the perineum, fissured and everted cervix, cervical catarrh, retroverted uterus, and both ovaries sensitive, enlarged, and prolapsed. This patient lived out of town, and could not have been treated by pads. The ovaries could be readily replaced, and November 21, 1885, an air-ring was inserted, to be removed at night for the hot douche, and to be returned in the morning. In December she no longer had constant pain. She had menstruated without the usual aching in the thighs, and with but two days of headache, during which no nausea was felt. By examination the fundus was found forward and the ovaries just at the brim, but not in a position to be compressed. In January she had no pain, and the ovaries were beyond reach. The air-ring was then exchanged for one of Meiggs' elastic pessaries, as recommended by Dr. Thomas, and as a more elegant instrument, and one probably more acceptable to the patient. At the end of two weeks, however, she returned in great distress, deeply despondent, with headaches re-established, and all of her old sickening pains. Examination showed a full return of the retroversion and prolapse. The air-ring was returned January 24th. February 2d, the pelvic distress had been relieved but the headache continued. In March she again felt well, having menstruated without any cerebral disturbance. In this case, also, the eversion of the cervix was reduced, so that the gaping os had given place to a smaller lengthened cervix, with a vertical division of its lips. The discharge also had ceased. The summer was passed at the seaside, and with the help of a well-fitting pessary she was perfectly comfortable and cheerful, and gained fifteen pounds during the period. Since her return she has *cleaned house*, however, and between the stretching implied by this exercise and a pessary which does not fit very well, she has had a return of pelvic distress, but no constitutional disturbances comparable with her former symptoms.

PROLAPSED AND SWOLLEN TUBES.

Case III. was an old case of retroflexion treated at the infirmary clinic. She was previously sterile, but had conceived while wearing a hard-rubber ring. Following her confinement, she had suffered from endometrial catarrh and was using the hot douche for this condition, one day, when she was suddenly seized with cramps, and during that night had a good deal of pelvic pain. On examination the left tube was found behind the uterus; swollen, the fimbriæ rounded, tense, and very sensitive. From the history it was supposed that the nozzle of the syringe had been placed against the cervix, and that the uterus, and possibly the tube, had been thus injected. The hard pessary was removed and an air-ring inserted; the patient continued her hot injections twice a day, discomfort was relieved, and in the course of a month she was again wearing her hard ring with ease. This was an acute condition and may prove nothing, except that acute conditions resolve more rapidly than chronic conditions do. Support of some kind, however, seemed necessary. The hard ring was not to be thought of, and even the violence of pushing up a pad was to be avoided. Without a support she would have had a persistently retroflexed uterus blocking up the pelvis, and interfering with circulation. Resolution could scarcely have occurred so rapidly, and with so little suffering, under these circumstances.

Case IV. was treated at the Demilt clinic. She was thirty years of age, a widow, one child thirteen years previously. Menstruation was scanty, lasting three days without pain. For four years she had had constant distress in the inguinal regions, which was even worse on lying down, but no constitutional symptoms were complained of. On examination the uterus was found in position and movable, but behind the uterus was what my clinical assistant called a nest of objects. Sometimes the tenderness would allow only the general fulness to be recognized, but at other times both tubes could be distinctly traced up to their respective horns. They were about as large around as the little finger, and at their extremities very sensitive. The ovaries did not appear to be implicated. This patient was under observation, at irregular intervals, during a year. The posterior pad was used, but the great sensitiveness would not allow it to be

effectively applied, and her employment of the douche was probably very irregular. No improvement occurred, and in August of the present year an air-ring was inserted. The patient then remained away six weeks, but finally returned for the reinflation of the ring. She stated that it had given complete relief, and added incidentally, that when first worn it had caused a profuse discharge, with a good deal of vulvar and vaginal irritation, but that this had ceased at the end of a few days. Examination, then made, showed but one tube where two had before been clearly made out. Apparently one had emptied itself at the time of its first elevation. The use of the pessary is continued, the patient presenting herself at the clinic only when inflation is required.

RETROFLECTIONS.

Two other cases may be mentioned. Both were cases of retroflexion which had defied our resources. For the sake of identification, the first of these may be called :

Case V.—She was twenty-seven years of age, married about a year, menstruation regular during this time. She came to the Demilt Dispensary for sterility with retroflexion, which was relieved by a Thomas pessary. She became pregnant while wearing this ring, but aborted at the end of the third month. After this abortion the uterus remained heavy, and it was found impossible to properly support it with any of the retroversion-rings. Upon every occasion the body would fall back over the posterior bar, and a series of dents were being worn in the wall of the uterus as the different pessaries were tried. An air-ring was introduced, and pregnancy shortly followed. The use of the ring was continued until the pregnancy had safely passed the fourth month and the danger of retroflexion was at an end.

Case VI. was probably a congenital retroflexion, as the uterus was simply doubled up. It had been under observation at the Demilt clinic for a year, and it never had been possible properly to support it with a ring. Its posterior wall showed the same series of dents, but more marked than in the other case. Dysmenorrhœa had always existed. June 14th, an air-ring was inserted. On the 17th the patient reported that she had been more comfortable with it than with any previous support; and July 16th, she reported that she had menstruated with but little pain; that she had not needed to go to bed, as was generally the case. Examination showed that the body was supported in a position at a right angle with the neck, this position being maintained after the removal of the ring; in every way a better showing than had been previously obtained.

Incidental results.—There have been several incidental results connected with the wearing of this ring that will also, perhaps, repay consideration. The first of these has been the disappearance of cervical catarrh. In Case I. the cure of the catarrh occupied about two weeks. This result has been fairly uniform. In another case, to test the effect of the ring, no other application was made. This case may be called Case VII. of this paper. There was a deep fissure with a tender cicatrix running down the posterior vaginal wall. There was sacral pain and an abundant leucorrhœal discharge. The eversion was very marked, and the eroded lips bled at a touch. This patient was at the time also suffering from pulmonary phthisis. She was overworked, and in an extremely emaciated and cachectic condition. At first each introduction and withdrawal of the ring brought blood, but at the end of two weeks, in spite of her general ill-health, the erosions were found healed, the eversion reduced, and the discharge no longer noticeable. With the stretching of the cicatrix the backache also had disappeared.

This reduction of the eversion and loss of the catarrh seems due to a moulding of the cervix to fit the aperture of the ring, when the everted parts take their normal position and the fissure the form of a vertical cleft. The ring then acts as a splint in holding these parts in position, and by actual compression, perhaps, produces the cure, acting with the beneficence of the bandage in the varicose ulcer in other parts. Its effect in controlling menorrhagia has suggested, further, some compression of the uterine artery. Shortening of the periods has occurred in a number of cases in which it was worn. Case I., finally thinking that she did not menstruate freely enough, would remove the ring in order to encourage the flow. It might be surmised that the cervix was occluded by it so as to prevent exit; but this was evidently not the case, as there was no pain connected with these periods.

A second incidental result has been the relief of symptoms in the cases of prolapsed ovaries. The women remain sterile. There is no reason to suppose that the ovaries have been restored to a healthy condition, and yet, both in the cases here reported and in other cases, the local pain, the deranged menstruation, the psychic difficulties, the disorders of the accommodation, and the headaches have disappeared. Apparently the symptoms were not due to the disease *per se*, but to the compression of this diseased part.

A third incidental result has been a discharge, apparently from the tube, noticed in a number of cases.

For some time it has appeared to me that if these tubes be sufficiently cleared, they may completely empty themselves through the uterus. Not long ago a posterior pad was applied in a young woman, having a large, low-lying tube. She returned with the complaint that, during the twenty-four hours following the application of the pad, she had had a profuse greenish discharge, which was excessively irritating, and examination showed the vulva and vagina in a highly congested and angry state. Another case once volunteered the remark that she always had a greenish discharge following the application of the pad. The pad was lubricated with vaseline in all of these cases. Glycerine never was used. The discharge never has been bland in my experience. It always excoriates, and is, perhaps, a sufficient explanation of the pelvic peritonitis which accompanies tubal affections.

A fourth peculiarity of the result of this ring has been that the flexions overcome by its use do not immediately return. It has then a curative tendency in these conditions. This is a remarkable fact for association with a pessary. The popular idea has been that a pessary, once worn, must always be worn; that is, that if it be removed, the displacement will return in an aggravated form; that its use tends to weaken rather than to strengthen the defective part. If we except the immediate reduction of retroflexions following childbirth, which are, as a rule, easily curable, this opinion is indorsed by my own experience. Retroflexions supported on the usual pessary tend to return upon its removal, and to be thus ultimately aggravated rather than improved. The opposite has occurred in cases wearing the inflated ring. A friend with a large gynecological experience spontaneously made to me this same remark. Said she: "A case of retroflexion and prolapsed ovaries upon which I have used this ring is now going without any support, and the uterus retains its position." For some reason, the broad ligaments regain a degree of elasticity and muscular tone. Possibly the removal of the ring at night has something to do with this result, for we know that while the too heavily weighted muscle contracts badly, it functions better if allowed to do some work than if not doing any at all. It is possible, then, that by our method of application we get not only the necessary rest, but also the necessary stimulus to good muscular tone.

Conservative gynecology.—Without touching upon the question of operation, there will remain many cases of catarrh of the tubes, to whom suitable support offers temporary relief by protecting the sensitive fimbriæ from compression, and also possibly the chance of a spontaneous cure by drainage. Of course this can only take place where proximal occlusion has not occurred. Apparently, however, proximal occlusion is not common in these cases, as a classic sign of salpingitis is an intermittent dis-

charge of pus. Failing the indications for operations, then, we need not abandon these tubes, but elevate them, and thus give relief, perhaps, and this chance of spontaneous cure.

The writer would like to protest, too, against leaving prolapsed ovaries alone, in the hope that the atrophy of the menopause will solve the problem which they present. It has seemed to her that cases of ovarian disease, cystic and other degenerations, occur more commonly where there has been a history pointing to a long-standing ovarian prolapse. Preventive gynecology merits attention. A better care of the woman after childbirth is required. Prolapsed ovaries are largely associated with retroflexion, subinvolution, a fissured cervix, and cervical catarrh. By examining the woman six weeks after her confinement this retroflexion can be easily relieved, and possibly prolapse of the ovaries prevented. Also, early operation upon the fissured cervix itself merits attention. If this repair can be safely done at the time of the confinement, all conservative considerations urge that it should be then done; as it will remove an absorbing surface during the puerperal period, as well as the lymphangitis and all its train of subsequent results.

Further, the young girl might be allowed to develop her broad ligaments so that her uterus will not wobble about so loosely. All of us have met cases where, with the perineum torn to the sphincter, the uterus remained in a firmly upright position; and the writer has previously referred to the fact that circus-riders apparently do not suffer from these displacements where their training has been commenced in early youth. Yet these women bear children, continuing their performances through the seventh month of pregnancy, and recommencing them shortly after their confinement has taken place.

How the conventionally restricted girl can obtain this development is, however, too large a problem for the writer of this paper.

The inflated ring.—In all of the cases detailed the simple ring without the tube attachment was used. These rings, as perhaps all know, have a lump of wax upon the inner surface of the rubber at a given point. Through this wax a hypodermatic needle may be plunged without injuring the usefulness of the ring, and by means of the needle the ring may be inflated, or air can be withdrawn. When the needle is removed the wax is to be gently compressed. In all of the cases here given there was a firm anterior vaginal wall, while the posterior vault was, as a rule, prolapsed. It was therefore found desirable to remove a little of the air from the fully inflated ring previous to its insertion, as this would allow its closer approximation to the parts. The anterior wall then would indent the anterior bar, while the posterior bar would spontaneously rise and buoy out the cul-de-sac posteriorly and upon the sides, the position when the patient stood being oblique, approaching the vertical in direction. The fully inflated ring will cause a feeling of weight in the perineum and irritability of the bladder, symptoms never complained of where a little of the air has been removed. In fact, it seems doubtful whether I could have obtained the advantages I have had from this ring had full inflation been insisted upon.

Another precaution has been, as already explained, the frequent removal of the ring. In cases where the patient has no pain when recumbent, it has been left out at night. It is then immersed in a solution of soda bicarb. or some disinfecting solution. The vagina escapes erosion by these intervals of rest, and the instrument does not become foul as when longer retained. As there is no danger of improper insertion, the woman removes and inserts it herself. All of our patients have been married women. Unmarried women would probably not be able to manage it; still, when but partially inflated, the ring may be folded into a spindle-shaped mass which enters the vagina without great difficulty. When inserted the patient assumes the knee-elbow position, when it rises spontaneously to its proper place. The ring requires reinflation every one to two weeks, and renewal every one to three months.

It has been objected that this is an exceptionally disagreeable ring to introduce and wear. Perhaps it is, but the patients for whom it was prescribed had been such sufferers that this objection became shadow-like and faded away in their presence. It is objected, that it erodes the vagina and takes on a fetid smell. As has been already remarked, this does not occur where it is removed at night and cleansed as directed. It is also said to distend the vagina and to destroy its elasticity. It has not, however, seemed to me more destructive than the prolonged use of pads.

The effect upon the cervix has suggested that this ring might produce atrophy if worn too long. This will probably have to be guarded against. While the external circumference of rings varies, the hole in the middle is about the same for all. As the cervix moulds itself to fit the hole, it follows that this uniformity is objectionable. A larger hole is desirable in some cases. Instrument makers tell us, however, that this modification cannot be lightly undertaken, as, from the intricacies of their manufacture, new models would be required which could only be introduced at a considerable expense.

The prolonged hot douche.—The hot *douche* forms an important part of the treatment in these cases. Some remarks have been recently published regarding the position to be taken by the woman when she must manage her *douche* alone. It has been found that she will not effect an injection of satisfactory duration when lying, and an injection when sitting over a bidet has been suggested. But a large proportion of the patients whom I treat do not have a bidet, and it has been my custom to have them place the hot water in their *pot de chambre*, to sit upon this vessel at a distance of about two feet from the wall, and then to tip themselves and the vessel so that their back rests against the wall. In all cases the Davidson syringe is preferred; and except where the leucorrhœa is a prominent feature, the same water is continuously used, the woman having at her side a pitcher of hot water with which to replenish it as it becomes cool. The patient then uses the *douche* ten minutes by the clock. The continuous use of the same water was adopted because it requires but one receptacle, while it insures the prolonging of the *douche* for the time indicated. As noted by a number of the correspondents referred to, this result cannot be obtained where the woman must rise to replenish the water in the midst of the *douche;* while it has been found that compliance with the smallest of the details here given can be obtained even among the most stupid of our tenement-house population. The position is, of course, not so desirable as the reclining position, but it is, perhaps, the best which can be devised for these people.

To RECAPITULATE.—The old inflated ring may be made useful: first, as a substitute for cotton pads in the treatment of prolapsed ovaries and tubes; second, to support the retroflexed fundus where it cannot be effectually lifted by other means; and third, for its decidedly beneficial influence upon cervical catarrh.

In the latter condition it reduces the hyperæmia by direct compression, or by direct compression aided by pressure upon the uterine artery. Pressure upon the uterine artery is suggested by the fact that the application of the ring as here suggested diminishes also the uterine flow. The peculiarities of application referred to are that the ring should not be tensely inflated, and that it should be used in cases having a firm anterior vaginal wall. As a preparation for trachelorrhaphy it cannot be too enthusiastically admired.

The results obtained by this ring in retroflexions contrast favorably with those of other rings, in that they tend to be permanent. It is, therefore, curative in its action, an admirable quality, even if true only in a slight degree.

As a support for ovaries and tubes, there is no instrument with which to compare it. Even though the superiority of the cotton pad be retained, where the patient must leave home, or for any reason cannot have her physician's constant attendance, this ring can be confidently used.

Other cases might have been detailed, but to avoid tediousness we have only given a number sufficient to show typical results.

For the detection of prolapsed or diseased ovaries and tubes, the Simms position is preferred, and examination with the patient upon the left side has been advantageously supplemented by examination with the patient upon the right side in some cases. In this position the prolapsed tube is not an indefinite mass, but can be recognized as in continuity with the uterus and traced up to its respective horn.

The preventive treatment of ovaries and tubes is in its infancy. Probably in a few years the measures here suggested will seem crudely ineffectual. Better means of combating the incipient stages of diseases in these organs must mark the course of gynecological progress in the future.

Clinical Department.

THE PREVENTIVE TREATMENT OF PUERPERAL ECLAMPSIA.

Dr. J. G. Palmer, of Oak Bowery, Ala., sends a communication upon the prevention of this most dreaded complication of pregnancy. Eclampsia he regards as essentially connected with uræmic poisoning, associated with, or dependent upon, albuminuria. He is inclined to believe that carbonate of ammonia is the real factor in producing eclampsia, associated with other pathological conditions of the nervous system so often manifested during pregnancy. He does not regard the albuminuria as due to inflammatory lesions of the kidney, but believes it is the result of mechanical causes, produced by pressure of the gravid uterus upon the kidneys, resulting in congestion of the renal vessels. The excrementitious products are retained, and urea is absorbed into the system and is converted through the action of some as yet unknown ferment into carbonate of ammonia. The writer believes that the convulsions may always be prevented, if the patient is seen in time, and he says that he has never yet seen a woman suffer from eclampsia who had consulted him for relief of the symptoms preceding puerperal convulsions. He reports the following cases:

"Case I.—In February, 1885, I was called to see Mrs. W——, aged thirty-six, the mother of eight children. I found her nearly blind, complaining that cobwebs were before her eyes, and screaming with the pain in her head. The face, hands, and lower extremities were very œdematous, and the patient had passed very little urine in the past thirty-six hours. The urine was loaded with albumen. I gave her twenty grains each of chloral hydrate and bromide of potassium, and ordered ten drops, gradually increased to twenty drops, of spirits of chloroform three times a day. I also ordered ten drops of tincture of digitalis to be taken before meals, and cascara cordial for the bowels. The next day I found the patient free from pain, with good vision, and the urine had increased in amount. In ten days the œdema had disappeared, and the urine contained hardly a trace of albumen. The woman was delivered at term of a living child, and had no symptoms whatever of her former trouble.

"Case II.—Mrs. D—— consulted me when she was eight and a half months advanced in pregnancy, complaining of dizziness, cephalalgia, obscure vision, and diplopia. The urine was scanty and albuminous, and the feet, legs, hands, and face were œdematous. I put her on ten drops of chloroform three times a day, and ordered ten drops of tincture of digitalis and twenty of fluid extract of buchu, to be taken before meals. I also advised her to take out-door exercise, to eat sparingly, and at short intervals, and to drink plenty of sweet milk. In one week the œdema was gone, there was but little albumen in the urine, the appetite was normal, and the bowels were acting regularly. The patient was delivered at term of a living male child, and had a very easy labor.

"Case III.—Mrs. G—— wrote me concerning some strange symptoms she was having. She was eight and a half months advanced in her first pregnancy, and her troubles were somewhat similar to those narrated above. As she was living at a distance, I could not examine her urine, but believed her to be suffering from uræmic poisoning, and sent her prescriptions for the chloroform and digitalis, telling her to keep her bowels acting freely. Relief followed immediately, and the patient was delivered at full term of a living child, and had no signs of eclampsia.

"I could relate the histories of several other cases of a similar nature, but these are sufficient to demonstrate the efficacy of the treatment. I am indebted to Dr. Griggs, of West Point, Ga., for suggesting the use of chloroform in these cases of uræmic poisoning if we may call it by that name. I shall not attempt to say how it acts, unless it be by preventing the decomposition of urea and the consequent formation of carbonate of ammonia, or by rendering the constituents of the urine more soluble and thus favoring their elimination through the ordinary channels. It perhaps has a sedative effect upon the nervous system, thus allaying much of the abnormal excitability. Although we must regard it as an empirical remedy, I can say that it has never failed in my hands, and others who have used it have met with equally favorable results. The use of digitalis in such cases is an original idea. I believe it is of great service as a diuretic, causing the excrementitious material to pass off with the urine, thus ridding the system of much that might be productive of evil. It is also of service as a heart tonic, assisting an already overworked and hypertrophied heart in the performance of its functions. I am not much of a believer in the cumulative action of digitalis, but I always try to use a reliable preparation. I can heartily recommend this mode of treatment to the profession, and I think it is of much greater value than is the use of veratrum, morphine, and calomel. The lancet should be used freely in cases of plethora or where much congestion is present, cases which are by no means rare."

THE TREATMENT OF WOUNDS OF THE BLADDER.

Dr. John Homans, Surgeon to the Massachusetts General Hospital, Boston, Mass., writes: "As bearing on the subject of the suprapubic operation for stone, which is being revived at this time, I may say that I have twice cut open the bladder during an ovariotomy. The first time was in my seventy-second case (one of dermoid tumor). The incision in the bladder was carefully sewed up with a continuous suture of silk, care being taken not to include the mucous membrane in the stitch. The bladder was closed tight, and a Sims catheter was kept in the urethra. The catheter was removed on the tenth day. The temperature was never above ninety-nine degrees, and there have never been any vesical symptoms at that time nor since. The second time was in my two hundred and tenth case—one of double papillomatous ovaries, the patient having been tapped eighteen times in five years for the removal of ascitic fluid. The wound of the bladder was more extensive than in the first case, and required twelve interrupted sutures of silk, in which the peritoneal and

muscular coats alone were included. A catheter was kept in the bladder seven days. After that time the urine passed naturally. In neither of these cases was the bladder drained through the abdominal wound. If the catheter in the urethra will drain the bladder, it would seem unnecessary to have another exit in the roof of the bladder. It would be well, however, to leave a drainage-tube in the integuments over the sewn-up bladder in case there should be any leakage."

THE USE OF COCAINE IN CORYZA.

Dr. Amory Chapin, of this city, writes: "I desire to attest to the beneficial results of cocaine in acute coryza. I have used the cocaine solution on a number of patients with throat and nose disease, who have been and are subject to 'cold in the head,' and have prescribed for their own use the four per cent. solution of cocaine whenever they were troubled with the disagreeable affliction, and it has been almost universally successful, often aborting the disease. I have found the combination of 'Dobell's Solution' with the cocaine work better even than the cocaine alone. I advise the use of the combination solution in an atomizer (hand bulb), and recommend that the solution be warmed to an agreeable temperature before being used in spraying the nares."

SUCCESSFUL PASSAGE OF A SAFETY-PIN THROUGH THE INTESTINES.

Dr. John C. Owens, of Plainfield, Ill., writes that, having just read an article in The Record, from the pen of Dr. Reed, on the subject of foreign bodies in the intestines, there is recalled to his mind the case of an eighteen months old child whom he was called to see some two years since. The little patient had not been well for some time; would seem to suffer pain at times, but as the source of the trouble could not be detected, the mother thought she might be mistaken. "The child grew worse, and I was sent for. On reaching the house, which was several miles in the country, I was informed that the child, a short time before my arrival, had cried out with pain while having a movement from the bowels. On examining the passage, great was the surprise of the mother to find a safety-pin about one inch in length, opened. Just when it had been swallowed was not known, but the mother thought a month or six weeks before, as the child had not seemed well during that time. No unpleasant symptoms followed the passage of the pin. To me it seems a remarkable case, from the fact that the child must have removed the pin from its clothing and swallowed it; and one could hardly imagine that a triangular object of that size, with a sharp point, could make its way through the intestinal tract of so small a child without lodging at some point, or causing more serious symptoms."

INTUBATION OF THE LARYNX.

Dr. D. A. K. Steele, of Chicago, calls attention to an error in the article by Dr. Northrup, on Laryngeal Diphtheria, which appeared in The Record of December 11th. The author made the assertion that there was no danger of the tube slipping down into the trachea, and said that such an accident had never been reported. Dr. Steele writes:

"I question the correctness of this statement, and am surprised that the pathologist of the New York Foundling Asylum should make it. Dr. Northrup seems to be perfectly familiar with the statistics of laryngeal tubage; as he condenses, classifies, and compares the reports of one hundred and sixty-five cases, yet singularly overlooks the occurrence of the accidental slipping of a tube into the trachea, reported by Professor Waxham as having occurred in his second case, and which was fully reported to the Chicago Medical Society, October 5, 1885, and published with other cases in the *Chicago Medical Journal and Examiner* for November, 1885. I call attention to this, as I believe it was the first recorded instance of the accident, and happened before the modifications of O'Dwyer's tubes by enlarging the shoulder and thickening the middle third of the tube. With the improved tubes, this accident would be much less likely to occur."

Progress of Medical Science.

Natural History of Tuberculosis and the Bacillar Theory.—Dr. R. B. Davy, of Cincinnati, has lately read two papers before the medical societies of that city, in which he thinks he has shown the infectious theory of tuberculosis to be supported in every respect by the natural history of the disease. He does not lay particular stress on the "bacillus tuberculosis," and speaks of the poison more as "tubercular virus;" but insists that, like all other organisms, it is a creature of heat and moisture. From the fact that its appearance and extension are only noticed to occur in confined spaces, and its disappearance most favored in unconfined spaces, he concludes that the danger of infection depends more upon quantity than quality of poison. After extensively discussing the natural history and climatic treatment of the disease, he comes to the following conclusions: 1. That tubercular phthisis occurs most frequently and most fatally in warm or hot regions, characterized by a non-porous soil, and the ordinary accompaniment of excessive humidity of atmosphere. 2. That it depends upon a specific organism, which can be made to produce the disease by inoculation. 3. That the key to the introduction and development of this organism in the system is ordinarily some form of irritation. 4. That the disease is plainly curable in all its forms except the acute, and even this may not always be fatal. 5. That to the predisposed it is communicable by infection through the medium of a polluted atmosphere. 6. That the infection depends upon quantity rather than quality of virus. 7. That on the open sea, where every condition favoring the development of tuberculosis is present, except the presence of tubercular spores, the disease speedily disappears. 8. That the nearest approach to perfect immunity from tuberculosis is to be found on high mountains, where, on account of extreme rarefaction and accompanying dryness of the air, the tubercular organism cannot exist.

Increased Means of Isolation Necessary in Checking the Prevalence of Scarlet Fever.—Dr. William Squire, in a paper published in the *British Medical Journal*, October 30, 1886, emphasizes the necessity of strict attention to isolation as a means of reducing the frequency of scarlet fever, especially in the larger cities. He says that diseases propagated by personal infection, such as scarlet fever and small-pox, have shown no diminution under extensive sanitary works, but require measures of isolation for their control; they are not checked by the great improvements in drainage and water supply that have proved so efficacious against the prevalence of diarrhœal diseases, and especially in diminishing the amount of enteric fever. He shows that the better classes can be generally isolated sufficiently at their own homes. But for the poorer people institutional facilities are necessary. He concludes by maintaining that in scarlet fever isolation is our only means of guarding against infection; we cannot provide for ourselves or others the immunity against this disease that vaccination affords against small-pox. No modified form of scarlet fever will insure against its recurrence in a more severe form. Were we to inoculate from a mild case of the disease, it is likely we should set up a severe, and it might be a malignant or fatal, form of the disease; however mild a form might result, others would be in danger of

being infected from it, and every case risks the well-known after-complications. The milder epidemics, conveyed through the medium of milk from the cow, would continue to spread and give rise to serious effects, if not so narrowly watched and exterminated. The modified disease lately discovered in the cow, though it produced but slight illness in some cases, did not do so in all. It is not an unusual thing to see scarlet fever happen twice, as it were: a child has sore throat and very little rash, or none, yet the illness is followed by desquamation, and it may be with other marked characteristic after-effects; a year or two after, this child is exposed to scarlet fever and has well-marked rash, a short illness, and no desquamation. Reinfection from scarlet fever has recently occurred, to my knowledge, in a child four weeks after a first typical attack; the second attack being the more severe and both followed by desquamation. If the unmodified virus does not confer immunity from a future attack, it is not likely that a modified virus will do so. How are we to protect by inoculation in a disease not clearly self-protective? The only answer here, as in diphtheria, is by preventing the intercommunication of the sick with the healthy.

The Alleged Curability of Tubercular Meningitis by Iodoform Inunctions.—Apropos of this subject Dr. Oxley, a correspondent of *The Lancet*, calls attention to the following points: Tubercular meningitis can only be diagnosed with certainty by post-mortem examination, therefore we must take with great caution any statement of a cure having taken place. It is simulated by typhoid, so as to be with great difficulty distinguished from it. The same may be said of suppurative pericarditis. Tubercular meningitis is an affection of the brain depending upon general acute miliary tuberculosis, and is usually accompanied by a deposit of nodules in and upon the lungs, pleuræ, liver, spleen, and kidney. Tubercular meningitis cannot be considered as a disease *per se*, although, owing to the fact that effusion into the ventricles of the brain, when excessive, produces death rapidly, it is convenient to consider separately this phase of tuberculosis. The effusion into the ventricles is caused by occlusion of the vessels by nodular growths of tubercle in their walls. If the iodoform rubbed into the scalp cured tubercular meningitis, then it must cure general miliary tuberculosis, as the head-affection is only one of the expressions of this general disease, which it modifies so as to make it hardly recognizable. Thus, in a case of tuberculosis complicated with meningitis and effusion into the ventricles, we have the temperature never above 100°; pulse from 80 to 100 up to the day of death, when it becomes rapid—156 or more; whereas in the acute tuberculosis, uncomplicated with effusion, we have a pulse of from 152 to 190, and a temperature of from 103° to 104.5°. In the first case, with meningitis, death takes place in from seven to fourteen days, and the patient is insensible most of the time; in the second, with the same general disease, minus the effusion, we have death occurring at the end of from fifteen to thirty days, and the patient is often sensible to the very last.

Tuberculosis and Scrofula.—About two years ago, as the result of some observations of his own, Dr. Arloing found that both the guinea-pig and the rabbit were affected by the inoculation of pulmonary tuberculosis, while glandular scrofula did not cause any visceral lesions in the latter animal. He did not, on this account, feel justified in believing the two affections to be absolutely distinct, but, at the same time, he was forced to the conclusion that if they had a common origin, its activity was markedly attenuated in scrofula. With this idea, he has since applied himself to find out whether it was possible to augment the virulence of scrofula to such an extent as to enable it to affect either animal indifferently. The guinea-pig is extremely susceptible to both tuberculosis and scrofula, and the latter invades its economy with such ease, and assumes such a malignant character, that it occurred to him that, by inoculating it through several generations in the guinea-pig, he might be able to increase its activity enough to overcome the resistance offered to its invasion in the organism of the rabbit. The experiment, however, showed that this was not the case. Among the bone and joint affections of human beings, known as localized tuberculosis and surgical tuberculosis, some are beyond the reach of art, while others are improved, if not cured, by surgical intervention; the latter are scrofulous lesions, the former tubercular, though of a milder form than that occurring in the lungs and serous membranes. Now, if rabbits and guinea-pigs be inoculated simultaneously with material drawn from lesions of this kind, it sometimes happens that the guinea-pigs develop the characteristic lesions of miliary tuberculosis, while the rabbits escape with a little localized suppuration, or a formation of fine granulations in the subcutaneous connective tissue, just as in the case of inoculation with scrofulous matter. But if other rabbits be inoculated with the tuberculosis thus developed in the guinea-pig, they almost invariably contract well-marked pulmonary tuberculosis. The organism of the guinea-pig is thus capable of augmenting the intensity of feeble tubercular virus, but is unable to do this for the virus of glandular scrofula. Dr. Arloing is of opinion that this curious disparity merits attention, more especially as the present tendency is to group scrofulous and tubercular manifestations under the same head, whereas there are undoubtedly very material differences between them—enough, indeed, to render further evidence of the identity of the virus in the two affections necessary before their common origin can be accepted.

Double Dislocation of the Jaw from Vomiting.—Dr. Elmer E. Curtis, of Rochester, N. Y., writes as follows in the *Medical Press of Western New York* for October, 1886: "On August 1, 1886, I was called to see Miss K——, whom I found suffering from gastro-enteritis of two weeks' standing. I found her much weakened and emaciated; prescribed for her, and in the evening was informed that she felt much better. On the following morning she felt so much improved that she, contrary to my instructions, indulged in a glass of beer, which produced a violent paroxysm of vomiting. I was summoned in great haste and informed that *Mary* (my patient) *had vomited her jaw out.* I found, to my great surprise, that she had produced double dislocation of the jaw, which I reduced with some difficulty. I report this occurrence because it seems to me to possess unusual interest, both in the manner of its production and from the fact that both sides were dislocated instead of but one, as is generally the case."

Granuloma Fungoides.—An account of a case of this rare affection has been published by Drs. Carl Hochsinger and Eduard Schiff, of Vienna. The disease began, in 1877, as a chronic eczema of the back, which gradually spread over the body. In 1883 the head was attacked, and soon became the seat of characteristic ulcerating nodules. The patient, a female, died in November, 1885. The authors describe the histology of the affection as a nodular formation of granulation-tissue replacing the normal structures of the cutis and the papillary body. A delicate reticulum supports the round cells, and in no part are any giant cells detected. The transition to healthy skin is gradual. The new-growth is not very vascular, and as it spreads it rapidly destroys the cutaneous capillaries. Described previously under such names as *lymphadenie cutanée*, *sarcomatosis generalis*, its alliance with specific inflammatory formations has been proved by the discovery of micro-organisms in the tissue. Rindfleisch gave it the name of *Mycosis fungoides*. Hochsinger and Schiff, in the present case, ascertained the presence of streptococci in the vessels, leading to the obliteration of the latter. They instituted a series of culture-experiments, which appear to prove that the micro-organism is distinct from the pyogenic forms.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, January 15, 1887.

THE COMING TREATMENT FOR PHTHISIS.

THE treatment of phthisis by medicated gaseous enemata, devised by Dr. Bergeon, of Lyons, has recently received the attention and measured approbation of Dr. J. Henry Bennett, who gives a full account of it in the *British Medical Journal* of December 18, 1886. We have already explained the general principles of Bergeon's method. He found that carbonic acid gas introduced into the system by the veins of the intestines was harmless, painless, and without special medical effect: in other words, it was a practically inert gas. He then medicated this with sulphuretted hydrogen, and the medicated gas was injected per rectum. The sulphurous gas was eliminated by the lungs, causing remarkably beneficial effects.

Dr. Bennett says: "Dr. Bergeon claims marvellous therapeutic effects for this medication. He says that he has been applying it for the last two years to all the cases of chronic pulmonary and throat disease that have come under his observation; indeed, in more than two hundred cases, although the experiments were made at Lyons, where the climate is bad, the results have been successful to a degree that has surprised and astonished him. He says that, in early phthisis, even in acute general phthisis, a form of the disease nearly always rapidly fatal, in two or three weeks there is generally an arrest, and in a few months a cure. Even in advanced, incurable phthisis, great amelioration is obtained. The pulse is lowered, the temperature falls, the night-sweats cease, the appetite returns, the expectoration rapidly diminishes, losing its purulent character, and the cough becomes less harassing and frequent. The amelioration, he says, is also rapidly obtained in advanced laryngeal phthisis, when all local or constitutional treatment has failed to give ease, or to arrest the ulcerative process. Asthmatic attacks are relieved with more certainty than by any other means, including the hypodermatic injection of morphine.

"These are very marvellous statements; but, coming from a scientific man of mature age, occupying a prominent orthodox position in a great medical centre (Lyons), and brought forward as the result of several years of trial and observation, they must command attention and counter-trial. Certainly, to pass from eight to ten or twelve litres of medicated gases through the intimate structure of the lungs, several times in the twenty-four hours, is a tangible reality, and a new departure in thoracic therapeutics. The entire structure of the lung is certainly reached; both the healthy and the morbid tissues are thoroughly searched out and permeated."

Bergeon has communicated his views to the Paris Académie de Médecine, and his method has been tried "with unexpectedly favorable results" in the hospitals of Paris, and at Lyons.

The injections are made twice daily. At first only about one litre of gas is used; and this amount is steadily increased. Great attention to details is needed; the sulphur must be pure, and no atmospheric air must be admitted.

Dr. Bergeon's method is novel, and with so many strong endorsements it plainly deserves an extended trial. It is not one that can be widely used at present, owing to the care and time needed for its application.

SHOULD PREACHERS PAY?

UNDER the above heading, Dr. George R. West, in the *Atlanta Medical and Surgical Journal*, makes a vigorous protest against the custom of not charging any fee for professional services rendered to a minister of the Gospel or his family.

The arguments put forward are in the main sensible and sound, although the picture is not quite so dark as Dr. West paints it. He believes that, in the interests both of the clergyman and the physician, the custom should be abolished. By it the clergyman is put at a disadvantage, because he cannot always have his choice of medical attendants, but must take one out of his flock. Then, since he makes no payments in money, he must feel a delicacy in calling upon the physician to the extent which he would often, perhaps, desire.

According to Dr. West, if a clergyman sends for his physician "at an opportune time, or happens in his office when he is idle, he will receive prompt attention with great courtesy. If, however, he sends when that physician is tired, or if the weather happens to be disagreeable—it being cold, wet, or in the night-time—the physician will stay at home, when he finds who wants him. If it had not been for that abominable custom which would prevent him from charging for his services, he would have rendered them."

We can hardly believe that such things as this often happen. No honorable physician would do his duty any the less thoroughly because he received no money equivalent. If medical services can never be conscientiously dispensed except on a commercial basis, then medicine is only a trade, after all, and its dignity is gone.

Dr. West goes on to say: "Under the existing customs, if a preacher or his family is being attended by a doctor in whom they lose confidence, it is a very awkward thing to demand that the doctor cease his gratuitous visits, and then call in another. If it was a money transaction, it could be accomplished in a business way."

He also states that it is not for the interest of the physician to treat the minister without compensation, although the reasons put forth are hardly so convincing.

Perhaps it is a fact that preachers do, as a rule, pay more, indirectly, than other people for their medical services. In our opinion, the custom does its greatest harm to the clergy; and it is with them that reform ought to originate.

THE EARLY HISTORY OF INTUBATION OF THE LARYNX.

Intubation of the larynx was suggested thirty years ago, but it is still generally believed to be an American idea, and, if we mistake not, it was independently conceived by Dr. O'Dwyer, of this city. Its early history, however, is almost a tragic one, and is worth recalling.

On September 14, 1855, M. Bouchut, then a young hospital physician and professor-agregé, described a method of treating laryngeal stenosis by intubation, thus avoiding tracheotomy. A commission was appointed to investigate the subject, and Trousseau was made its secretary. He read his report two weeks later, and presented the following conclusions :

"Tubage" of the larynx in certain cases of acute laryngitis can by retarding asphyxia prove of curative value.

In certain chronic diseases of the larynx it will allow one to delay tracheotomy, and sometimes relieve or cure the patient.

In the treatment of croup it delays asphyxia, and allows a more easy introduction of air and agents capable of modifying the diphtheritic inflammation.

It can only very rarely supplant tracheotomy, which is the principal means of opposing croup when medical measures fail.

The last conclusion was practically an extinguishment of M. Bouchut's views and method; but it was most actively supported in the discussion which followed, and M. Bouchut was, it is said, most virulently and ungenerously attacked. The discussion finally became so warm that Trousseau went to the tribune; then, in the language of the *Gazette des Hôpitaux*, "it was no longer a discussion, it was an execution!"

M. Bouchut was attacked in his character, and in his honor, and his idea was actually hounded out of existence. The ingenious but unfortunate physician found all the official avenues to promotion barred against him. His career was in fact almost ruined. By force of character and perseverance, however, M. Bouchut has won a name in pædiatrics, and it must be a matter of no small satisfaction to see his idea now revived and warmly indorsed by many excellent authorities.

A WORD OR TWO ON WARM CLOTHING.

At a time when there is "a nipping and an eager air" the question how to keep warm presents itself in many urgent phases. In the matter of properly clothing the body, or, in other words, of conserving animal heat, the physician is consulted as much as upon any point within the range of hygienic requirements.

There is no doubt that wool stands at the head of the materials out of which clothing is made. Its virtues depend upon its being a poor conductor of heat; its porosity, allowing the passage of the exhalations from the skin; its power of absorbing moisture and giving it up slowly and gradually.

As a non-conductor of heat woollen materials have been shown by exact experiments to rank first, although with them must be placed certain furs and the down of birds. After these come silk and cotton, while linen ranks last.

The porosity of flannel as compared with that of other materials has also been determined by experiments showing the pressure required to force air through them Flannel is nearly twice as porous as linen, more than twice as porous as silk, and seventy times as porous as glove-leather. Both flannel and silk take up water slowly and give it up again slowly. Owing to the openness of the texture, and the hydroscopic power of the fibre, a considerable amount of water can be held in its meshes; more than twice as much, in fact, as can be taken up by cotton or linen. The slow evaporation of water from flannel as compared with linen is well known and often observed. Rags of linen, not flannel, dipped in water are used to cool the fevered brow or allay an inflammation. Linen imbibes moisture most quickly, cotton next, and wool last.

Woollen clothing is universally used by athletes during exercise. This is a good plan if, as is the rule, thin flannel is used. In very hot weather linen or cotton, however, is better during the exercise. After exercise the body continues to perspire, and the perspiration, becoming vaporized, cools and may chill the surface. If dry flannel is now put on, however, the vapor is condensed in its meshes, the latent heat restored, and an agreeable feeling of warmth results.

Woollen clothing is not so good as leather and fur for those exposed to cold winds. Our country readers in the North know well the comfort, and even necessity, of buckskin jackets and fur coats.

Woollen clothing promotes the activity of the skin; and it is much revered by the rheumatic, with good reason. Redness in flannel is supposed to give it additional virtues.

Red flannel is generally an irritating material, owing to its coarseness and sometimes to the dye. This more or less peppery quality furnishes the sole basis for its popularity.

The color of a fabric affect its properties as a material for clothing in two ways: the absorption of heat and of odors. Cloths absorb heat and odors in the following order: black stands first, then come blue, red, green, yellow, white.

The wearing of flannel is believed by some to lessen the risks of malaria. That it does do so, except in a very indirect way, is improbable, though Parkes is inclined to give some credence to Andrew Combe's opinion in favor of this view.

Many persons cannot wear pure wool next to the skin, owing to its slightly irritating properties. For these, silk is perhaps a tolerably good, though a most expensive, substitute. A combination of cotton with the wool can be all but too easily found, which sensitive skins can easily endure.

DISPENSARIES AND OUT-PATIENT DEPARTMENTS.

At the time when every new hospital begins to feel that it must have an out-patient department for the benefit of the sick poor and its annual report, the experiences recently furnished in London may be studied with profit. At a meeting held under the presidency of Sir Andrew Clark, to discuss the question of provident medical associations and the treatment of the sick poor, some very vigorous attacks were made upon the out-patient depart-

ments. Mr. Timothy Holmes said that it was in great measure to the abuse of these so-called charities that the provident dispensary system had failed to meet expectations.

A resolution was passed "that the attention of the governing bodies of hospitals, and other public authorities, be called to the necessity for some check on the indiscriminate provision of medical treatment at hospitals and dispensaries."

A second resolution was adopted, to the effect "that in the opinion of this meeting the future medical attendance on the poorer classes ought to be conducted on the principle of sick assurance."

DEMOCRACY AS A CAUSE OF FINANCIAL DEPRESSION AMONG PHYSICIANS.

In a series of seven articles, published in *The Provincial Medical Journal*, upon the causes of low fees, much stress is laid upon the fact that of late years persons from the very lowest strata of society had in increasing numbers entered the profession. This class was, as a universal rule, poor; starting in practice they were obliged from the beginning to earn enough to live on. The consequence was low fees. It is part of the glory of our country that persons of the humblest class have here the right and opportunity to rise to the highest positions.

But we can also recognize that this prevailing desire to rise often springs from discontent and laziness rather than honest ambition, and often leads to placing persons in positions which they signally fail to fill.

The ranks of the profession in this country are remarkably full of persons who started from the very bottom educationally, socially, and financially. It is greatly to the credit of the American character that it shows such power of cultivation and development, and that the American physician illustrates this better almost than any other class. There is a tremendous developing and educating power in medical work.

At the same time, our profession shows plainly to what an extent it is recruited from the very poor; and we can trace to this fact, especially in cities, much of the very small-fee system, and the consequent hard work and financial straits of the physician.

COUNT TOLSTOI ON PHYSICIANS.

Count Tolstoi may be a great novelist and a remarkable thinker, but if he never thought anything more original than the following, which is going the rounds of an admiring press, he should give up an unfruitful habit of systematic ratiocination. He says:

"This is where the strength of the physician lies, be he a quack, a homœopath, or an allopath. He supplies the perennial demand for comfort, the craving for sympathy that every human sufferer feels, and of which the germs exist in the child. See a baby that has given itself a blow; it runs to its mother or its nurse to be kissed and have 'the place' rubbed; and it actually suffers less for the pity and caress. Why? Because it feels that they are bigger and wiser than itself, and have it in their power to help it. So the doctors were of a certain use to Natacha when they assured her that she would be better after taking the pills and the powders from the shop in the Arbatskaia, which were put up in a neat little box, costing one ruble and seventy kopecks, and were to be dissolved in boiling water, and taken every two hours."

We do not know what was the matter with Natacha, but if it was constipation, or a real hard stomach-ache, for example, we would put blue pills and paregoric against a sense of the personal bigness of the doctor every time.

"Such gentle physic given in time had cured her" much more quickly than the most expansive sympathy. We are not disputing that there is much truth in Tolstoi's remarks, but so far as this is the case they are exceedingly trite and commonplace. It is just eighteen hundred years since Patronius Arbiter remarked:

"*Medicus nihil aliud est quam animi consolatio*" ("The doctor is nothing but a consoler of the mind"), which is exactly the point made, with much diffuseness, by the Russian count. Certainly his quoted passage, though having a fine literary quality, must be classed as a true *castana vesca*, and should only be quoted hereafter with this proper explanation of its ripe antiquity.

THE RELATION OF MUSCULAR ACTION TO ANIMAL HEAT.

This problem has always been one of the most interesting ones of physiology. It was long ago definitely settled that muscular action, with its attendant metabolic changes, was the great source of bodily heat. When a muscle contracts there is, to use the modern phrase, a decomposition of the explosive contractile substance. Part of the liberated energy is manifested as muscular movement, and the rest is changed into heat. The blood returning from the seat of activity is darker than that supplied thereto. It has become laden with carbon dioxide gas, which is one form of ash of the combustive process for which oxygen is the fuel.

Some interesting experiments on this point have recently been reported by M. Quinquad to the Biological Society of Paris. The muscles of a dog's leg were made to contract twice a second by means of an induced electric current of known strength. The contractions were kept up over a period of three-quarters of an hour. After the first five or six minutes the temperature of the animal invariably rose, the rapidity of increase varying in different species. Respiration was increased from twenty-two to over one hundred per minute, and became somewhat irregular. This irregularity continued after the passage of the current had ceased.

In the first experiment the rectal temperature before the stimulation was 102.6° F. The current was allowed to pass in all thirty-five minutes. After twenty minutes the temperature had risen to 105.8° F. Respiration was increased, and the animal panted as if he had been running a long distance. After fifteen minutes more the current was stopped, but the panting still continued. Two hours after the commencement of the experiment the animal died, with a temperature of 107.6° F. Another fact noted was the diminution in glucose in the blood from the side stimulated over that in the blood from the other side. In the former it was .70 gm., and in the

latter 1.20 gm. This is not, however, a new physiological observation.

The general conclusions which can be drawn from M Quinquad's observations are these: First, that local muscular action brought about by electrization can induce a general hyperpyrexia which may verge on danger; second, that in death resulting from electrization the overproduction of heat may be one element of fatality; and, thirdly, that after exposure to cold, with its attendant depression, the application of electricity is a means of restoring heat to the system by causing its internal production. We think that this last remark needs limitations. If a patient is in a state of great exhaustion from prolonged exposure it is doubtful whether the advantages of this method of treatment would counterbalance its disadvantages. However, it is a therapeutic procedure worth remembering.

MEASLES AND DIPHTHERIA IN NEW YORK CITY.

The epidemic of measles, and the somewhat unusual prevalence of diphtheria, in this city have frightened many nervous people to a quite unnecessary extent. The impression has been created that both measles and diphtheria are malignant. This idea, however, is an erroneous one, as the reports of the Board of Health show. The ratio of deaths in cases of measles is about the same as is usually reported. The same is true of diphtheria, of which the number of cases reported weekly is only in slight excess of what it was a year ago. Besides this, in the last two weeks the number of cases, both of measles and of diphtheria, has been decreasing. In the four weeks of December, 1885, there were 355 cases of diphtheria reported, with 157 deaths; in the corresponding weeks of last year there were 471 cases and 207 deaths, the mortality ratio being thus actually less than a year ago. In the three winter months of 1885–86 there were 134 cases of measles and 12 deaths. In December of 1886 there were reported 1,979 cases of measles and 232 deaths.

The Utility of the Medical Art.—"The best way to ascertain whether the art of medicine is worthy of the respect, the confidence, and the gratitude of mankind," writes Dr. H. W. Boone, in the "Report of the Hospital for Chinese," at Shanghai, "is to compare the present status of the medical sciences in the West with what China has to offer. Here we have a vast nation, numbering nearly one-fourth of the whole population of the habitable globe. She boasts of a civilization older than that of the most ancient nation of the West. She has a gigantic body of literature, her traditions extend to the dawn of the human race. What do we see? Her medical practitioners are steeped in ignorance and superstition; they know nothing of any one of the exact sciences; they have no accurate methods of diagnosis, and the remedies in use among them are puerile. Of surgery, they have none. The enormous mass of preventable or curable disease, of suffering, of agony, and death endured by this countless multitude every day and every year is the most powerful witness in the world to the utterly incalculable and overwhelming power for good that modern medicine and surgery have to offer."

News of the Week.

New York Pathological Society.—At the anniversary meeting held January 12, 1887, the following were elected officers for the ensuing year: T. Mitchell Prudden, President; W. P. Northrup, Vice-President; John H. Hinton, Treasurer; Wesley M. Carpenter, Secretary; John C. Peters, Editor; Drs. W. Mendelson, J. C. Peters, H. Marion Sims, L. E. Holt and W. H. Porter, Committee on Admission and Ethics; Drs. G. C. Freeborn and W. P. Northrup members of the Committee on Publication.

Dr. William Perry, of Exeter, N. H., died on January 11th in the ninety-eighth year of his age. He was the oldest graduate from Harvard College, having graduated in 1811, and was the sole survivor of the passengers on Fulton's first steamboat ride on the Hudson, eighty years ago.

Rheumatism, Rank, and Rotundity.—It has been suggested that rheumatism is the pathological appendage to American greatness. President Cleveland has it, Blaine has it, and Logan had it.

Dr. James E. Kelly, a Dublin physician of some political prominence, now on a visit to this city, was tendered a public dinner last Monday, by some of his political friends.

Pasteur's Latest and Worst Failure has just occurred, according to recent despatches. The patient, whose finger was nearly bitten off, was taken promptly to the Rue Vauquelin. At the end of twelve days, hydrophobia was manifest, ending under conditions to convince Professor Peters, who kindly reports the failure at once to his colleagues of the Académie de Médecine, that the malady was due to the operation.

Infectiousness of Tetanus.—Dr. Wing, a veterinary surgeon, treated a horse which died of lock-jaw. He unfortunately scratched his hand at the post-mortem. Tetanus developed, and he died of the disease. The *American Veterinary Review* thinks that the case was an illustration of Verneuil's view that equine tetanus may be conveyed to man.

Rough on Fevers.—This is the popular name suggested for antipyrin, antifebrin, and thallin.

Notes from St. Louis.—Dr. F. W. Wisseler, an old and well-known practitioner, failed to report a case of diphtheria, and has been proceeded against by the board of health.

A Blind Physician, Dr. Robertson, has been elected by the Conservatives to fill the vacancy in the Brighton (England) district. He had no opposition.

The Southwestern Medical Gazette is the title of a new medical monthly, published at Louisville, Ky., and edited by Dr. M. F. Coomes and Dr. J. B. Martin, with a long list of eminent collaborators. The *Gazette* shows evidence of good journalistic experience.

Dr. Fordyce Barker has been elected President of the Medical Board of the Woman's Hospital of the State of New York, in this city.

The Useless Dispensary.—Many of the friends of the Presbyterian Hospital consider the building of the new dispensary a useless bit of extravagance, and are withholding their subscriptions accordingly.

Gout Brought on by Starvation.—Mr. Jacques, the English fasting-man, has brought his experience to a close on the twentieth day of his fast. Curiously enough, says the *Hospital Gazette*, the eighteenth day of his fast was marked by a typical attack of the gout in one big toe. This is so contrary to the popular notion of the etiology of gout that it was received by the public with a certain amount of incredulity. The attack, however, caused nothing more than a little passing inconvenience, and at the close of the experiment he was in very good health and spirits. He weighed one hundred and sixteen pounds, as against one hundred and thirty-eight pounds at the beginning, and had thus lost twenty-two pounds in about the same number of days.

Does the Prescription belong to the Patient?—In answer to this question, as asked by a correspondent, we say: The prescription is the property of the patient, on the principle that what he pays for is his.

No Patent Medicines for Russians.—The Russian government has decided to prohibit the importation of patent medicines; the published list of prohibited articles contains eight hundred items.

Toys for Hospitals.—Seven years ago, the editor of *Truth* started an exhibition of toys, made by its readers, for distribution among the hospitals. At the last exhibition, over fifteen thousand toys were sent in for exhibition and distribution. The idea is a good one, and might well be carried out in this city, in connection with some of our charitable organizations. There are six or seven hospitals which treat or care for children exclusively, besides eight or more hospitals which have children's wards.

Another Medical Centenarian.—According to Spanish journals, there is at present in Logroño a medical man, Don Rosendo Recondo, still in considerable practice, and in the enjoyment of good health, who, if he lives till next February, will be one hundred years of age.

States' Rights and Hospital Internes.—A most extraordinary restriction has been established by the Legislature of Louisiana, according to *The Southwestern Medical Gazette*. The eminent body of local patriots in question voted $90,000 to Charity Hospital, "provided that only Louisianians should be permitted to compete for positions on the staff of the hospital!"

Electrolysis in Membranous Laryngitis.—Dr. F. E. Waxham, of Chicago, reports a case of membranous croup with very severe symptoms of laryngeal stenosis. An intubation tube was introduced, and made the negative electrode by connecting it with a platinum wire. A current of eight cells was passed. The symptoms improved, and the child recovered.

An Expensive Medical Attendant.—The New York correspondent of a Philadelphia paper tells the interesting story of a very wealthy lady of this city, well known in society, who is suffering from Bright's disease. She has engaged a medical man, who is most known, however, as a surgeon and a poet, to visit her twice daily for $50,000 a year. Doubtless, a person could be hired to have Bright's disease himself for that sum.

Dental Anæsthesia.—M. Georges Vian claims to have solved the problem of local anæsthesia in dentistry. After numerous trials of solutions of different strengths he has found that the soft parts about the maxillæ may be rendered completely insensible by the use of cocaine, associated with a two per cent. solution of carbolic acid. Five minutes before operating M. Vian dissolves five centigrammes (one grain) of hydrochlorate of cocaine in fifty centigrammes (ten drops) of the solution, and injects it into the gums, half-way between the neck and the extremity of the root of the tooth. Half of the solution is injected on the palatine and the remainder on the labial side, pressure being made by the finger, when the needle is withdrawn, to prevent the exit of the fluid. Anæsthesia is perfect in three minutes. The quantity of cocaine advised by M. Vian seems somewhat large, but it is said to have been so used in eighty-seven cases without causing any unpleasant symptoms."—*Paris Correspondent of Lancet.*

A Rare Form of Fracture.—At a meeting of the Academy of Medicine of Ireland, recently, Mr. E. H. Bennett exhibited a cast and specimens of a rather rare accident, viz., simultaneous fracture of both clavicles. There are only about eighteen examples known, and in eight cases only did union take place.

Hospital Superintendents Resigning.—Dr. W. N. Wishard has recently resigned his post of hospital superintendent of the Indianapolis City Hospital. Dr. A. J. Willard has recently resigned the superintendency of the Mary Fletcher Hospital, at Burlington.

In Boston they do not say stomach-ache, but "gastric neuralgia." But it gets there all the same.—*Life.*

The San Diego County Medical Society is the title of a new medical society recently organized in San Diego, Cal. All regular physicians residing within the county, and practising according to the recognized ethics of the profession, were cordially invited to unite with the society.

Hydatid Cyst in the Scrotum.—Dr. Philip E. Musket, of Sydney, New South Wales, sends us an account of a case in which a hydatid cyst was found in the scrotum. It formed a tumor about the size of a large emu egg. Dr. Musket believes this to be the first recorded case of a scrotal cyst from this cause. He adds: As to unique situations for hydatid disease in my own experience, I have found, after death, in Douglas' pouch a cyst the size of an orange in a young girl who died of cardiac trouble. Had opportunity permitted an examination during life, it would doubtless have given rise to some difficulty in diagnosis. I have also been present at an autopsy where a cyst was met with in the pericardial sac. While house surgeon at the Sydney Hospital I saw a cyst, the size of a hen's egg, situated over the left deltoid muscle, which was taken to be an ordinary fatty tumor till it was exposed by the scalpel.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Annual Meeting, January 6, 1887.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE ANNUAL REPORTS

Showed an increase of the General Permanent Fund, of the Library Fund, and of the Building Fund, besides creation of the Krackowizer Prize Fund, during the last year; also a notable prosperity in the library and in the scientific and general interests of the Academy.

OFFICERS FOR THE ENSUING TERMS

were elected as follows: *President*, Abraham Jacobi, M.D.; *Vice-President*, William H. Draper, M.D.; *Trustee*, Everett Herrick, M.D.; *Member of Committee on Admissions*, Henry E. Crampton, M.D.; *Member of Committee on Library*, F. P. Kinnicutt, M.D.

DR. L. EMMETT HOLT read a paper on

THE ANTISEPTIC TREATMENT OF SUMMER DIARRHŒA.

The speaker stated that he did not undervalue other methods of treatment than the use of drugs, such as careful feeding, change of air, etc., but the object of the paper was to discuss what additional measures were useful.

All the causes of summer diarrhœa—excessive heat, improper or artificial feeding, and bad hygienic surroundings—united to produce a dyspeptic condition, which was really at the bottom of nearly all of these cases. The age showed it could not be heat alone, for the disease was not frequent at the most tender age—under six months. Of 431 cases, only twelve per cent. were under six months, while fifty-nine per cent. were between six months and two years. The explanation was that under six months most of the children were fed at the breast. Improper and artificial feeding was quite as important as heat, as Hope had found in 591 fatal cases that only 28 had no food but the breast.

Heat depressed vital energy, increased decomposition in the streets and sewers, and thus vitiated the atmosphere; but, most of all, it produced in the food given to young children putrefactive changes before it was taken into the stomach.

This was especially likely to occur with milk. One instance was cited of every one of twenty-three healthy children being taken in one day with diarrhœa from bad milk.

Closely related to this subject were the poisons produced from food, or ptomaines. Brunton had stated that most of the alkaloids produced from the decomposition of albumen caused diarrhœa. It was believed that many of the nervous symptoms in summer diarrhœa had their explanation in the effects of these alkaloids. This was true especially where the discharges were abruptly arrested, either spontaneously or by opium. They were to be looked upon as a form of toxæmia.

The inflammatory changes found in the intestine were to be looked upon as a consequence of the diarrhœa rather than the cause of it. The most marked lesions were always found in the cæcum and sigmoid flexure, just where the irritating substances were longest detained in their passage.

Immense numbers of bacteria were found in the discharges, but no sufficient evidence had yet been adduced to establish the existence of a special microbe as a causative agent.

The indications for treatment were four: 1. To clear out the bowels. 2. To stop decomposition. 3. To restore healthy action in the alimentary tract. 4. To treat the consequential lesions.

It was proper to begin with a cathartic in all cases unless the stomach was very irritable. Castor-oil was by far the best. If much vomiting were present, a copious injection of water, enough to wash out the colon, should be given.

Many mild cases could be cured by the oil alone, provided suitable dietetic regulations afterward could be carried out. In severe ones it gave only temporary benefit.

For the second and third indications an antiseptic should be given and the diet carefully regulated. The best antiseptics were sodium salicylate and naphthalin. The former should be given in doses of one to three grains, according to the age of the child, every two hours, and the latter in about double the dose.

If vomiting were present, all food should be stopped for from twelve to twenty-four hours, and thirst quenched by thin barley-gruel or mineral waters—cold, and in small quantities.

Unless the child were upon the breast, in which case it should, of course, be kept there, it was better to *withhold milk entirely*. Wine-whey, animal broths, expressed beef-juice, or even raw beef, could be used and were usually sufficient.

To meet the fourth indication—*i.e.*, to treat the lesions—astringents by the mouth were useless, with the possible exception of bismuth. The diet should be as carefully looked to in chronic cases as in acute. The antiseptic should be continued, to check fermentation and decomposition in the intestine, and the large intestine should be washed out once a day with pure water or a weak antiseptic or astringent solution.

Attention was called to the fact that, except opium, nearly all the drugs which had held their place in the treatment of this disease were antiseptics of more or less power. Bismuth, calomel, the mineral acids, iron and silver salts were cited. Pure antiseptics had been used in the treatment of diarrhœal diseases since 1846. Creosote was first employed, and with great success both in England and in this country. Ten or fifteen years ago salicin was largely used, especially in the South, with uniformly good results, particularly in chronic cases. The use of salicylic acid and its salts, the bichloride of mercury, and naphthalin was also referred to. The last was of latest introduction and seemed likely to prove of very great value, perhaps the most valuable of all.

Notwithstanding the successful results obtained by antiseptics, the great majority of the text-books still advocated the old plan of the use of opium and astringents as fifty years ago. An inquiry into the public practice of this city showed that in fourteen institutions and dispensaries, where it was estimated that twenty-five thousand children were treated yearly for diarrhœal diseases, the main reliance was still upon opium, bismuth, chalk-mixture, and castor-oil.

The speaker had tabulated 300 cases of his own treated by such remedies. Of these, 50 per cent. were cured; 27 per cent. improved; 18 per cent. unimproved; and 7 per cent. died. During the past year he had treated 81 similar cases by an initial dose of castor-oil, followed by salicylate of sodium, these being the only drugs used. Of these, 84 per cent. were cured; 7 per cent. improved; 7 per cent. unimproved; 1.2 per cent. died. Forty-four cases were treated by naphthalin, usually preceded by the oil. Of these, 67 per cent. were cured; 15 per cent. improved; 13 per cent. unimproved; and 2 per cent. died. Resorcin was used in a similar manner in 27 cases. Of these, 55 per cent. were cured; 22 per cent. improved; 22 per cent. unimproved; and none died.

The duration of the disease in these cases before treatment was about the same in each class. The duration of treatment in the cured cases was much shorter by sodium salicylate than by the use of opium, astringents, etc. In cases of long standing the very great superiority of the salicylate and naphthalin was clearly shown. Resorcin was much inferior to the drugs just mentioned.

The following conclusions were drawn from the paper:

First.—Summer diarrhœa is not to be regarded as a disease depending upon a single morbific agent.

Second.—The remote causes are many—heat, improper and artificial feeding, bad hygiene, etc.

Third.—The immediate cause is the putrefactive changes which take place in the stomach and bowels in food not digested, which changes often are begun outside the body.

Fourth.—These products may act as systemic poisons, or the particles may cause local irritation and inflammation of the intestine.

Fifth.—The routine use of opium and astringents is not only useless, but, especially at the outset, may do positive harm; since, by checking peristalsis, opium stops elimination and increases decomposition.

Sixth.—Evacuants are to be considered an essential part of the antiseptic treatment.

Seventh.—The salts of salicylic acid and naphthalin are the antiseptics which, thus far, seem to be best adapted to the treatment of diarrhœal diseases.

Dr. R. W. Wilcox spoke especially with reference to the use of naphthalin in diarrhœa in adults. Since reading Rossbach's paper in the *Berliner Klinische Wochenschrift*, in November, 1884, he had used naphthalin in thirty-two cases, nearly all being in adults. He had come to feel as much confidence in the use of this drug, under certain circumstances, as in the use of mercury or the iodides in syphilis or of quinine in intermittent fever. As mercury and quinine may fail to accomplish their work if used without observance of a few well-known precautions, so naphthalin may fail if improperly employed. The most frequent cause of failure has been the use of too small quantities, less than sixty grains daily being a needless waste of a very good medicine. He had given up to one hundred and twenty grains during the twenty-four hours in divided doses, usually in starch capsules with a small quantity of oil of bergamot to conceal the somewhat unpleasant odor. If the impurities of the drug are removed by washing with alcohol, no such untoward effects as have been occasionally reported in the journals will occur. Frequently during its administration the urine will assume a smoky color, resembling that of acute nephritis, but a careful examination will fail to detect either albumen or casts.

In chronic diarrhœas he had used naphthalin as the only drug in twenty-one cases. Nearly all degrees and varieties had been represented; some could be traced back to an acute process, others were the result of improper food or followed debilitating diseases.

He related one case: James D——, messenger, eighteen years of age, came to him, complaining of a diarrhœa of over two years' duration. Its commencement was in the second summer previous to his first visit. The assigned cause was overindulgence in unripe or spoiled fruit. The trouble had continued through the following winter, with intervals of cessation, and had been aggravated the following summer. Since summer his loss of flesh, previously considerable, had increased, his tongue was heavily coated, the appetite poor; his discharges were five to six daily, unformed, varying much in amount, sometimes watery, very foul-smelling, much gas, no tenesmus, no blood; pain at times, but no fever. Although he was in a deplorable condition, and so long as his work remained severe and his food unsuitable recovery seemed impossible, by the use of sixty grains of naphthalin daily the number of movements were reduced, within a week, to two daily, and, for the first time, became formed and devoid of odor. About six months afterward he reported that after three weeks he had discontinued his medicine, having had no further necessity for using it.

In *chronic dysentery* he had used naphthalin in seven cases, with excellent results. The most interesting case was that of James C——, sixty-six years of age, who contracted dysentery while serving in the Federal army in 1862–64. He had never been free from the disease except for a few weeks at intervals. He could remember no day during which he had not had more than one passage. He was emaciated, with sallow, dirty skin, marked tenesmus, abdomen painful on pressure, red tongue, pulse very feeble, no appetite. His stools averaged seven movements daily—slimy, blood-stained, of extremely foul odor. This man had ninety grains of napthalin daily, and at the end of a month he would have hardly been recognized as the same man. Four months after he reported himself so much improved that he considered himself a well man.

His experience in the diarrhœa of *typhoid fever* had been limited to two cases: Charles B——, 25 years of age, and John F——, 16 years of age, both of whom he saw for the first time in the third week, the diagnosis being thoroughly established. In both there was commencing tympanites; diarrhœa, to the extent of six to ten passages in the twenty-four hours. Naphthalin was administered up to sixty and ninety grains in the day, with the result of "stiffening up" the motions and reducing them to two daily. The odor of the stools, in both cases, was lost. In fact, he felt so confident that the intestinal canal and, consequently, the fæces were disinfected that he did not take any other precautions. He also directed attention to the antipyretic effect of this drug. In general, the use of antipyretics in typhoid fever he considers unsafe; but if the practitioner was thoroughly imbued with the idea that he must use an antipyretic, let him use naphthalin, which reduces temperature, indirectly, by disinfection of the intestine. Its safety compared favorably with that of antifebrin, thallin, antipyrin, etc. Whether typhoid fever had ever been absorbed by this or any other drug he did not pretend to say; but if it could be accomplished, in his opinion, naphthalin, by its vigorous action upon the contents of the alimentary canal, should tend to that result.

Of the use of naphthalin in acute intestinal catarrhs, and in the diarrhœas of children, he had had no experience. In the diarrhœa of chronic tuberculosis he had had no opportunities for experiment. In all his cases of diarrhœa evidences of tuberculosis in other organs were sought for, but were not found. He would emphasize the claims of naphthalin as *the* drug to use in all cases in which it was necessary to disinfect the alimentary canal, as in typhoid fever, intestinal catarrhs, and dysentery, because it seems to be, of all the drugs at our disposal, the most certain, and at the same time the one most free from danger.

Dr. Andrew H. Smith thought that the best method of treatment, in the cases considered by Dr. Holt, was by the administration of antiseptics. He believed that the success that attended the use of many domestic remedies depended upon their antiseptic properties, such as the different mints, etc. So far as his experience went, it was in exact accord with the views advanced by the author of the paper.

Dr. John C. Peters believed that he was among the first to call summer diarrhœa a hot-filth disease, and he regarded Dr. Holt's views concerning the use of antiseptics as correct. Bacteria will live in tincture of opium and in calomel, but are killed by acids, and the mints are among the best remedies at our disposal.

Dr. Van Santvoord had had considerable experience in the treatment of summer diarrhœa occurring in children in Randall's Island Hospital, and it coincided with Dr. Holt's. This diarrhœa should be considered as primarily an indigestion, and the subsequent changes depend upon fermentative processes, and the indications seem to be plain. With regard to the use of opium, he restricted it to the cases in which the passages were watery and frequent, and he gave it hypodermically in the form of a solution of morphine guarded by atropia; about $\frac{1}{250}$ of a grain of sulphate of atropia to five minims of United States Pharmacopœia solution of morphia (gr. j. to $\frac{\text{ʒ}}{}$ j. of water). Bismuth he regarded as an antiseptic, and had been accustomed to give a dose of it after each feeding. He had a general impression favorable to flushing the entire colon with an astringent solution containing an alkali. He thought that the addition of

a small quantity of salt to an astringent injection would contribute toward its reaching a larger surface than it would otherwise do.

The President remarked concerning bismuth that he regarded it as an antifermentative, a view that he had held for many years. Dr. Holt had only incidentally mentioned dietetic treatment, but at the same time had been emphatic in what he had said, and with him the President agreed. Milk should be avoided. It was impossible, in his opinion, to relieve a severe attack of summer diarrhœa without stopping the feeding of milk for a few days, perhaps a week or more. Raw white of egg mixed with barley-water had served him best as a substitute. Raw beef should be avoided because of its liability to give to the child a tape-worm, and the beef tape-worm was the most difficult to remove. He had seen a few cases of diarrhœa in adults in which naphthalin did some good for some time and very speedily.

Dr. Geo. L. Peabody had come to look upon naphthalin as a very valuable addition to our means for treating a variety of intestinal complaints. Since the publication of Rossbach's paper he had been using it in the early cases of typhoid fever in the New York Hospital. He was very confident that he had seen several cases aborted by the use of naphthalin, given in quantity varying from sixty to eighty grains in twenty-four hours. He then gave, briefly, the history of two cases in which the patients, with well-marked symptoms of typhoid fever, were convalescent within fourteen days.

Dr. Carpenter referred to the antiseptic treatment of diarrhœa in adults—dysenteric cases from the army, tuberculous cases, etc.—by the administration of a domestic remedy—an acid in the form of what is commonly known as "old cider" or "hard cider," a glassful three times a day, and by the use of salicin, a remedy that had been employed many years for this purpose.

Dr. John C. Peters said that it was important to use pure water, and that distilled water would cure a great many cases of dyspepsia and diarrhœa without the aid of any other treatment.

Dr. Holt, in closing the discussion, remarked that Dr. Caldwell had used salicylic acid in the treatment of the diarrhœa of phthisis, with results far superior to those that had been obtained by the use of opium or astringents.

With regard to irrigation of the bowel, he regarded it as a very valuable accessory to the antiseptic method.

Dr. T. R. Varick's resignation was accepted, and on motion he was made a non-resident Fellow.

The Academy then adjourned.

Inhalations of Ether in Non-expansion of the Lungs.—Dr. John H. Jones (*New York Med. Journal*, August 21, 1886) recommends *the inhalation of ether in non-expansion of lung* due to adhesions of pleural surfaces, occurring after pleurisy with purulent effusion, in aponeurosis of children, and asphyxia neonatorum. After absorption or artificial evacuation we frequently find that a long-continued effusion in the pleural sac is followed by destructive changes in the corresponding lung. Many remedies have been tried with the object of expanding the air-vesicles and preventing the occurrence of carnification, but with unfavorable results. The most effectual treatment heretofore has been that of breathing compressed or rarefied air. But by far the best method in Dr. Jones' experience is inhalation of ether. He has used it on three patients with very flattering results, and can confidently recommend it to the profession as the best means of dilating the air-vesicles and restoring the lung to its natural state. If the adhesions have not been of too long standing, and are not very dense in structure, they will certainly yield, and, once overcome, will be permanently obliterated. The inhalation should be pushed to complete narcosis. The inhalation of ether is also recommended in the asphyxia of the new-born.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE OPERATIVE TREATMENT OF POPLITEAL ANEURISM—THE CAMPBELL DIVORCE CASE—MEDICAL LIBRARIES—THE HOSPITAL SUNDAY FUND AND THE FINANCIAL POSITION OF OUR HOSPITALS—THE BROWN LECTURES—EPILEPSY AND ITS METHOD OF PRODUCTION—SOME RECENT DEATHS—THE SOCIETY OF APOTHECARIES—CHRISTMAS AT THE HOSPITALS—TOYS FOR HOSPITAL CHILDREN.

London, December 21, 1886.

A great change in the operative treatment of popliteal aneurism seems indicated by a short discussion on the subject at a recent society meeting (Medical and Chirurgical Society). In a paper by Mr. Savory, on the effect upon the femoral artery of its ligature for the cure of popliteal aneurism, an analysis of twenty-six museum specimens was given. Seventeen of these were complete, and of these seventeen the artery was pervious throughout in thirteen cases, being closed only in four cases, and even in these the closure was only partial. Fifteen out of the seventeen were cured. In these the artery was pervious in eleven and partially closed in four. In two the operation had failed to cure, and the artery remained pervious in both. Mr. Savory gave details of two cases of his own. In one the femoral artery was tied in Scarpa's triangle. There was a slight return of pulsation on the third day. A year later the aneurism had returned. Rest and elastic bandages having been tried without benefit, the popliteal artery was tied in the upper part of the popliteal space and the operation was completely successful. In another case the artery was tied first in Scarpa's triangle, then in Hunter's canal, and finally in the upper part of the popliteal space. Mr. Savory said he should in future be disposed to adopt the latter operation in preference to ligature of the femoral. Mr. Hulke, Mr. John Wood, and Mr. Thomas Smith all concurred with Mr. Savory in this view, and their utterances will doubtless receive due consideration from British surgeons, representing as they do the opinions and practice at three metropolitan hospitals. Mr. Ballance remarked that in his experiments on the ligature of large arteries in their continuity in animals he had never found the artery obliterated for any distance beyond the ligature.

After a trial occupying eighteen days, and with adjournments spreading over a month, the Campbell divorce case terminated at a late hour last night. Into the general features of the case I will not enter. Suffice it to say that, on the one hand, Lord Colin Campbell (a younger son of the Duke of Argyll, and therefore a brother-in-law of the Princess Louise) sought a divorce from his wife on the ground of adultery with four co-respondents. These were respectively the Duke of Marlborough (who has been divorced by his own wife), a distinguished army officer (General Butler), Captain Shaw (of the Metropolitan Fire Brigade), and Mr. Tom Bird (a member of the medical profession). Lady Campbell brought a countercharge of adultery against her husband, and as by the English law adultery alone is not a sufficient plea when the wife is the petitioner, cruelty was also put forward on the ground of a verdict in a previous trial, in which the wife had (on that plea) obtained a judicial separation. I will not pollute your columns with the shameful particulars of the case, but there are a few points of medical interest. One is that the cruelty of which the wife complained, and on the ground of which she had obtained a judicial separation, consisted in the fact that her husband had imparted to her a venereal disease (gonorrhœa), which had produced a severe illness—endometritis and pelvic cellulitis ensuing. After infect-

ing her he persisted in continuing cohabitation, and, on her refusal, said he would leave her. She then said she must make clear the reason, and brought the suit for a judicial separation. I believe it is the first case on record of a judicial separation being granted for the special kind of cruelty in question, though most medical men could furnish examples of its perpetration. The verdict of the lower court was, however, confirmed by the Court of Appeal. Such being the case, the Judge in the present trial repeatedly told the counsel that he must tell the jury they could not go behind the former verdict. Another feature of medical interest was the defence set up by Lord Campbell to the charge of adultery against him. The only piece of evidence brought forward by him was that of two obstetric physicians, who had examined the girl accused and found her *virgo intacta*. This was an unusual defence to a charge of adultery, but one which evidently had great weight in spite of the doubt thrown on the medical evidence in cross-examination. Lord Campbell had the advantage of having among his counsel one (Mr. Finlay) who had been educated as a medical man, afterward leaving it for the law. An unpleasant feature of Mr. Finlay's concluding speech was the tone in which he spoke of Dr. Braxton Hicks, who, he said, had shown himself to be a thorough partisan of Lady Campbell's. I may just note that the result of the trial has been that all the charges have broken down, and that the parties therefore remain just where they were before—viz., judicially separated.

In the matter of medical libraries London is singularly ill-provided. A more or less complete library is, it is true, to be found in connection with each of the medical schools, but none of these even approach completeness in their contents. Their use is also restricted to the alumni and teachers attached to the schools. There are two or three very good medical and scientific subscription libraries at rates of subscription ranging from a guinea a year upward. The only example of a free, large, public library of medical literature is that of the College of Surgeons. This collection includes about forty thousand volumes. But these can only be perused at the library, the rules not allowing books to be taken home. This restriction places would-be readers at a great disadvantage, as Lincoln's Inn Fields, although in the very heart of legal haunts, lying as it does almost under the very shadows of the new Law Courts, is by no means of easy access from most parts of London. To dwellers at the West End, the library of the Royal Medical and Chirurgical Society offers many advantages. It is not free, as the privilege of borrowing books from it is restricted to town members of the society, who each pay three guineas a year and six guineas entrance fee. On the other hand, eight volumes at a time may be taken home for perusal. The library includes nearly as many volumes as that of the College of Surgeons, and as regards modern medical literature, is reputed the best in London. I must not omit to mention the library of the Obstetrical Society, which is a very good one of works on obstetrics. Its use is restricted to members of the Obstetrical Society. The College of Physicians also possesses a library, but it is very inferior to that of the College of Surgeons.

The sum raised this year by the Hospital Sunday Fund is £40,000, being £6,000 more than was raised in 1885. This is cheering, and looks as if hospitals were being more liberally supported by the public. Now for the other side of the medal. Guy's Hospital is one of the three largest metropolitan hospitals, but is richly endowed, its income formerly amounting to upward of forty thousand pounds a year. Thomas Guy, however, directed his trustees to invest the money in land, and the fall in value of land during recent years has taken £15,000 a year from the income of the hospital. Pay patients have been received to eke out the income, but this source of income has not produced sufficient to stop the leak. Being an endowed hospital it has few subscribers. The financial position of the institution is now so bad that it has been determined to make a special effort to raise a fund of £100,000 to keep it open. A public meeting for this object was held yesterday at the Mansion House and subscriptions to the amount of £17,000 announced. Other hospitals also lament the decadence of their funds.

London, December 28, 1886.

In Professor Horsley's recent "Brown Lectures," at the University of London, he has continued the consideration of the subjects taken up by him last year. The subject of epilepsy was discussed at some length in several lectures. Experimental research showed, he said, that epilepsy could originate from discharges in the motor cortex of the brain and from discharges in the bulbo-spinal centres. The disturbance might begin in any part of the encephalon, and, if in the perceptive centres, this would readily explain the affection of intelligence. A detailed account was given of the various investigations made to ascertain the existence of special convulsive centres either in the pons Varolii or in the medulla oblongata. The existence of these was considered as not proved. All the ascertained facts could be harmoniously interpreted otherwise. Professor Horsley said he believed that all the convulsive (tonic and clonic) phenomena could originate from the ordinary bulbo-spinal centres already existent for the purpose of carrying out normal mechanisms. Tonic or clonic spasm could be produced by any motor nerve centre, but the combination and sequence of tonic-clonic could originate only from the cerebral motor cortex. It was an interesting problem whether the clonic spasm of cortical epilepsy was the effect of cortical or bulbo-spinal discharges. The experiments of Nothnagel and Brown-Séquard (in which convulsions were set up by direct and reflex irritation respectively of the nerve-centres) were described and criticised. Dr. Hughlings Jackson's views of the representation of movements in the hemispheres were then considered and combated. Dr. Jackson had maintained that each hemisphere represented both sides of the body, and according to this theoretical view it would be possible to evoke convulsions of the whole of the body by stimulating one motor centre. But however probable these views might be theoretically they obtained no support from clinical or experimental evidence, which simply showed that one-half of the body was represented in the opposite hemisphere with but few exceptions. Professor Horsley then gave in detail certain experimental and clinical evidence which seemed to show conclusively that, as a rule, each hemisphere convulsed its own (the opposite) side of the body. In hemiplegia, if the motor cortex were completely cut off, the limbs remained permanently paralyzed. Then, again, in unilateral fits there was no necessary spread to the opposite side of the body. In one monkey with unilateral cortical fits induced by electricity, the muscles of the back and belly were convulsed only on the one side, showing that even such muscles as are supposed to act bilaterally, and to be closely united spinally, did not do so in cortical fits. The lecturer considered this a strong argument against Dr. Broadbent's explanation of the escape of certain groups of muscles in hemiplegia. He then gave an account of some experiments performed by himself. The conclusions all round, he said, were very emphatic that convulsions due to cortical discharge were evoked in various groups of muscles by nerve energy proceeding from that centre in each hemisphere which is in relation to each group of muscles, and that in generalized epileptic convulsions both cerebral hemispheres were involved.

Two well-known British—though not English—practitioners have just joined the majority. One of these was Dr. Ebenezer Watson, of Glasgow. He was surgeon to, and lecturer on, Clinical Surgery at the Glasgow Royal Infirmary. He made numerous contributions to medical literature, mainly on laryngeal surgery. The other was Dr. Lyons, of Dublin, formerly M.P. for that city. Dr.

Lyons was well known in Dublin, where he practised for many years as a physician. His published works and papers are numerous. The most important among these were his "Treatise on Fevers," and his "Report on the Pathology of the Diseases of the Army of the East." The latter was based upon his experience as Chief Pathological Commissioner to the army in the Crimea, and was issued as a blue-book by the government. Dr. Lauchlan Aitken has also recently died. Dr. Aitken for many years past has resided at Rome, where he practised as a British physician. Another death worth a passing word is that of Dr. Fergus. For thirty-seven years he occupied the responsible post of medical officer at one of our large public schools—Marlborough College. Dr. Fergus will be remembered as the first resident medical officer ever appointed to a public school, although now there is, I believe, no public school without its medical officer in residence. Since Dr. Fergus' appointment, in 1849, the duties of medical officers of schools have become much more arduous and extensive. With the advances in sanitary science they have been expected to assist in the prevention as well as in the cure of disease. It is not too much to say that many modern improvements in school hygiene are due to the efforts of their medical officers. An Association of Medical Officers of Schools was formed a few years since.

The request of the Apothecaries' Society for affiliation has been refused by the Universities of Oxford, Cambridge, and Manchester (Victoria University), and is still *sub judice* by those of London and Durham. Meanwhile the society have considerably strengthened their position by electing Mr. Brudenell Carter as their representative on the General Medical Council. Mr. Carter is Ophthalmic Surgeon to St. George's Hospital, and an able speaker and writer, having been, indeed, for many years a frequent contributor to the both medical and general press.

Christmas festivities at the hospitals are in full swing, though somewhat sadly marred by the numerous "accident cases" brought to the hospitals as the result of the severe storm two days ago. One of the most remarkable features of hospital Christmases within the last few years has been the distribution of toys on a gigantic scale to the sick children. This was started in 1879 by the editor of *Truth*, who asked his readers to send in toys for the children of the hospitals. This they did to the number of a thousand. This year more than fifteen thousand toys have been sent, nine thousand new sixpences, fourteen thousand crackers, and two thousand pots of jam. The proprietors of Willis Rooms lent their premises free of charge for the gratuitous exhibition of this enormous collection, which has since been dispersed among the sick children of the various hospitals, workhouses, and other institutions in the metropolis, and has, I trust, gladdened the holiday season for many a little sufferer.

OUR PARIS LETTER.

HYPNOTISM—PROFESSOR POTAIN—THE SUCCESSORS OF CORVISART—M. PETER AND THE MICROBISTS—THE THEORIES OF ANTI-PARASITIC TREATMENT.

PARIS, December 24, 1886.

HYPNOTISM, with its terrible consequences, is the order of the day, and is greatly occupying the public mind both in and out of the profession. It has been scientifically established that, by certain procedures, one can develop in some persons a state of artificial somnambulism, analogous to natural somnambulism, and that in this state they lose their will and their personality, become passive instruments in the hands of magnetizers, and are accessible to all sorts of hallucinations and of suggestions. This state is aggravated by the momentary loss of the memory. The subject does not retain the least recollection of what passed during hypnosis, and all cerebral spontaneity disappears to such an extent that the person would fatally execute all the orders that may be given him, their execution, however, not being immediate, and may be delayed several hours, several days, and even several weeks. The great danger that may result from such practices is that the repetition of these performances would provoke hysteria, and subsequently mental aberration, as has been already observed. Owing to the grave disorders that have been officially established, public exhibitions of hypnotism have been interdicted in Germany, Italy, and Austria, and so they ought to be everywhere else. In a moral point of view the practice of hypnotism is not the less to be deprecated, as instances have occurred in which the subjects have become the victims of the most odious attempts without being the least conscious of what had taken place. Moreover, public security would also be in danger if the practice of hypnotism be authorized for other than medical reasons. For instance, a person hypnotized may, without his knowledge, be robbed of all his fortune. He can be made to sign any written document, and it would be almost impossible to discover the fraud. The subject may also be made to receive "suggestions" which would push him to commit all sorts of offences and crimes—robberies, forgeries, incendiarisms, assassinations, poisoning. The hypnotized subjects may thus become the blind and unconscious instruments in the hands of the most dangerous malefactors. These reflections are to be found in a pamphlet just published, under the title of "Les Suggestions Hypnotiques," the author of which, M. Frederic Delacroi, a Judge at the Court of Assizes, at Besançon, from his position would be considered a great authority on the subject.

In taking possession of the Chair of Clinical Medicine of the Charity Hospital, in succession to Professor Hardy, Professor Potain delivered a most interesting discourse on the history of clinical medicine in France. But before broaching the subject he pronounced a very eulogistic compliment to his predecessor, and bore testimony to his reputation as a shrewd observer as well as to his powers of diagnosis and his success as a clinical teacher. The lecturer then took a retrospective view of French clinical medicine, and stated that it originated as a real science in that very hospital where he was then lecturing, La Charité, and was founded by the illustrious Corvisart, whose name is perpetuated not only in history, but also by a tablet in the amphitheatre of this hospital, to which he was attached for many years—from 1788 to 1809. M. Potain defined the term clinique as "the study of medicine at the bedside. It is even the base of medicine; it is the commencement as well as the end. But the teaching of medicine at the bedside of the patient could not be possible without a hospital. This is why clinical history is intimately connected with that of hospitals. Before the creation of these institutions, clinical teaching did not really exist." Many eminent men succeeded Corvisart at the Charity Hospital, and we have only to mention the names of Laënnec, Louis, Piorry, Bouillaud, to have an idea of the superiority of French clinical medicine.

Professor Peter, who succeeded Professor Potain at the Hôpital Necker, as Professor of Clinical Medicine, inaugurated his course by a lecture on "The Clinical Aspect of Contemporary Medical Doctrines." He began with Laënnec and his important discovery of "mediate auscultation." He then referred to the discovery, about the middle of the last century, of "mediate percussion," by Avenbrugger, of Vienna, but its establishment as a means of diagnosis is really due to Corvisart. Laënnec was considerably influenced by the teaching of Corvisart, and to him (Laënnec) must be attributed the credit of having introduced into contemporary medicine the scientific methods employed to this day as means of more precise diagnosis than have existed before. After having gone through the different phases of medicine to the present time, Professor Peter entered into his campaign against

the microbian theory, which is the latest innovation in the etiology of disease. M. Peter, true to his principles, endeavors by every possible means, and on every occasion that presents itself, to prove the falsity of the position taken up by microbists, not that he would ignore the existence of parasitic diseases, which, fortunately, are few in number, and are well known even without the aid of the microscope ; but what he does emphatically deny is the rôle of the microbes in certain diseases, for it is still a mooted question as to whether the microbes found in the organism are the cause or the consequence of the disease with which they are coincidently found connected. Consistent with their theory, the microbists have adopted a new line of therapeutics, but even if their deductions be correct their antiparasitic treatment must prove a failure, as it is simply impossible for any medicine, whatever be its degree of tenuity, to reach or affect the microbes in any way, much less to dislodge them from the position that they occupy.

To illustrate his meaning, M. Peter recalls that in cases of pneumonia, which is now considered by some to be a parasitic disease, injections into the lungs are advised, without considering how irrational such a medication would be ; for, hypothetically, the pneumococci being parasites, the parasites being essentially of a repullulating nature, it is sufficient that ten, two, or only one pneumococcus be not touched by the injection for the malady to persist by the repullulation of one or more surviving micrococci. Those who practise on this theory boast of the absence of accidents, but they forget that the powers of resistance in certain patients is greater than they imagine. Koch's theory of the parasitic treatment of cholera is equally untenable ; but remarking that his comma bacillus of cholera ceases to reproduce itself in a moist medium, he actually had the absurd idea of destroying the bacilli by thirst, and did not hesitate to advise the inhabitants of Marseilles, who were being decimated by cholera, to cease watering their streets. Other practitioners, again, to have the pendant to surgical antisepsy, have imagined *medical antisepsy*. Their idea may be generous, but it is purely chimerical, for surgical antisepsy reposes on this notion, that the wounded patient is healthy, but is the subject of a wound. In medicine disease already exists, and when the physician is called in, the organism is already infected, and if admitting it is by the microbe, the latter has already taken up its position. The *antirabic inoculations* are as severely handled by M. Peter, for he condemned them as being irrational in principle and inefficacious in reality, for after having been announced with éclat, they are known to have lamentably failed, even in the hands of the discoverer of the method. In conclusion, M. Peter advised his hearers not to attach much importance to these questions —which are more calculated to divert the physician from his real position—but to attend exclusively to *the history of patients*, for the physician has not to do with maladies but with sick people ; that is to say, of individualities reacting, as well as they can, against morbid accidents. This is what he terms true clinical medicine.

OUR VIENNA LETTER.

(From our Special Correspondent.)

MEETING OF THE IMPERIAL ROYAL SOCIETY OF PHYSICIANS—A CASE OF ACTINOMYCOSIS—TERATOMA OF THE KIDNEY—ERYSIPELAS AND INFLAMMATION.

VIENNA, December 12, 1886.

AT a recent meeting of the Imperial Royal Society of Physicians of Vienna, Dr. Hochenegz, assistant to Professor Albert, demonstrated a very interesting case of primary abdominal actinomycosis, which was in treatment at the surgical clinic of Professor Albert, in the General Hospital. The patient, aged forty-three years, sustained, some time ago, a lesion on the hypogastric region by a heavy hammer, which fell on the side of his body. After the lapse of fourteen days he recovered, but after nine months noticed a swelling in the inferior abdominal region, and was not able to work. Examination showed a sinus in the umbilical region, which was secreting pus, in which the characteristic grains of the actinomyces fungus could be discovered. This sinus had been first noticed three days before the patient was admitted into the hospital. The patient was losing flesh constantly. No swelling was to be seen on the neck ; the condition of the thoracic viscera seemed to be normal, and the expectoration contained none of the fungus in question. A large, distinctly limited tumor, quite immovable on its base, was present on the abdomen ; the skin over the swelling was not adherent. The region, upward of the prostate, offered a great diffuse resistance to the touch. The fæces and urine were normal. Dr. Hochenegz remarked that the above-mentioned lesion might have given origin to an adhesive peritonitis, and this to the formation of a solid callosity, into which the actinomyces fungus took its way out of the intestine. He, furthermore, added that, taking into consideration the good results obtained by operation in such cases, as for instance, in the cases reported by Esmarch, it would be tried at Professor Albert's clinic, either to remove the whole tumor, or the morbid parts, by means of the sharp spoon.

Professor Coskor remarked, on this occasion, that he had seen two cases of actinomycosis of the funiculus spermaticus in animals, and that six other cases belonging to this class were on record. At the same meeting Dr. Foltanek showed an interesting specimen taken from a child, aged eleven months, which represented a teratoma of the kidney. The latter was but slightly changed by this formation. The teratoma presented a great number of cysts, with serous, purulent, and hemorrhagic contents, respectively, which were lined with cylindrical epithelium. The child had died of an intercurrent disease—lobular pneumonia. A clinical diagnosis of sarcoma of the kidney had been made.

On two subsequent meetings of the same Society, Dr. Hajek read a paper on the relation between erysipelas and inflammation. I wish to refer to you this paper at some length, as I think that it will be of interest for the readers of THE MEDICAL RECORD.

Dr. Hajek said that he had undertaken the researches in question in order to determine whether the streptococcus of erysipelas differed morphologically, pathogenically, and in its mode of growth, from the streptococcus pyogenes ; whether, as to pathology, each of these two species was pathogenic in its proper way, viz., whether the first produced only erysipelas, the latter only phlegmons. He first combated the statements of Resenbach and Hoffer as to the differences of these cocci respecting their form and cultures, and said that the slight differences in the aspect and the quickness of growth were of no importance. The different cultures of these microorganisms did not show any striking differences, but, nevertheless, they were not at all to be looked upon as identical forms. This became evident from the experiments upon animals which the speaker had performed for the purpose of determining the pathogenic influence of the cocci in question. He, for this purpose, inoculated two series of rabbits with the cultures of the streptococcus of erysipelas and the streptococcus of phlegmon, respectively, after the cutaneous and subcutaneous method, and found some differences in both instances. In the cases of inoculation with the streptococcus of erysipelas, he, for the greater part, observed a wandering redness with swelling of very slight degree. In a small number of these cases there presented itself, after inoculation, an inflammatory nodule, which either underwent resorption or suppuration. An intense swelling, together with the wandering redness, was but seldom observed. As to the streptococcus pyogenes, the greatest number of the rabbits thus inoculated showed an intense swelling with suppuration ; the latter was present when the inflammatory process had reached its highest degree. An intense

swelling without suppuration was rare. There was never present a wandering redness without swelling, which was observed in most cases of erysipelas; only the most severe cases of erysipelas resembled the usual forms of phlegmon.

Dr. Hajek, therefore, and probably correctly, concluded that the cocci in question were of a different nature. But it was not the difference of the pathogenic behavior of these two species of streptococcus to which he attributed the greatest importance. The reason for which he felt justified in stating that there was an absolute difference between the coccus of erysipelas and that of inflammation was the result of his histological researches. The histological changes in erysipelas first manifested themselves in an inflammation of the lymph-vessels, later on in an inflammation of the interstices of the connective tissue, and only in the most intense cases the tissue around the lymph-vessels is concerned too. As to the cocci of erysipelas, they were to be met with only in the lymph-vessels, and at the most to a very slight extent, also, in the interstices of the connective tissue. The living tissue formed, in general, no particularly favorable soil for the development of the streptococcus of erysipelas. Moreover, the behavior of the latter, in the progress of the morbid process, was a passive one, as it was to be found only where it was transported by the lymph-current. The behavior of the streptococcus pyogenes to the living tissue was, however, quite different. Here, the lymph-vessels and the interstices of connective tissue were filled with close colonies of cocci, the cellular infiltration either being absent, or developed to only a very slight degree. Moreover, the streptococcus pyogenes formed close chains everywhere in the cutis, penetrated it in all directions, and perforated even the walls of the blood-vessels. Hence the streptococcus pyogenes had the disposition to represent itself in the living tissue in the form of colonies. Dr. Hajek remarked that the difference of the behavior of these cocci in the living tissue was a marked one; for, even in the most intense cases of erysipelas, the cocci were always to be found only in a proportionately small number, and this only in the lymph-vessels.

Dr. Hajek added that in future, in cases of complications of erysipelas with other affections, it will not be permitted to consider the second disease which complicates the case of erysipelas as dependent on this, but that it will be necessary to prove that the second affection was, indeed, produced by the streptococcus of erysipelas. He, for instance, succeeded in doing so in a case in which pleurisy formed the complication of erysipelas, as the streptococcus which was found in the pleuritic exudation, inoculated on five rabbits, produced only the typical complex of symptoms of erysipelas. In a second case, however, in which pneumonia was the complication of the disease in question, no such etiological connection could be discovered between the two affections, as there was found in the infiltrated lung only the "diplococcus pneumoniæ," and no streptococcus.

THE COUNTRY DOCTOR AND HARD THINKING.

To the Editor of The Medical Record.

Sir: Accept my thanks for the kind words in behalf of "the country doctor" in your issue of December 18th. Your paper every week reaches the homes of many of these quiet and, in many instances, obscure gentlemen; and while they read, study, and—permit me to suggest—*think* over the matter in its columns, as a rule they are too tired, fatigued, and exhausted to contribute the results of their observation and experience.

In addition to the infinite perplexities of practice, you gentlemen who dwell together in great cities know little of our every-day "transportation problems." We exhaust much brain-tissue in *thinking* about how to reach our patients. Long and dreary rides, by day and night, summer's heat and winter's cold, sand and mud, wind and rain, is our common lot. This, however, is sometimes varied in a way to make city doctors think!

I was called to visit a man ten miles from home. I had to cross a river; there was neither bridge nor ferry. But this is no great matter to country doctors. I thought of a waterman, hunted him up, tried to hire him to row me across. He significantly pointed to a "storm" about to break, and was astonished that a man of my "learning" should attempt to cross.

Watching this "storm" for several miles of my ride afforded abundant "thought." The little speck afar off on the horizon was an "element" of trouble. Many calls had to be made, miles had to be ridden, three good horses for changing at intervals, no dinner, and a very late supper, I *thought*, would get me through the day, barring accidents. On my early ride before seeing my first patient for that "big day," the accidents struck, the storm and the boatman struck. Having given some "thought" to boats in my rural life, I took the oars, and with the boatman's "For God's sake, doctor, don't go! my boat can't live in such a storm," I went with difficulty, saw the patient with double pneumonia, returned in safety. The boatman declined pay for the use of his boat, saying, "a doctor who risked so much for a patient could not pay him for a boat."

Again, I borrowed an "electric battery" from a brother physician about twenty miles off by the road, and promised to return it on a certain day. Rain, hail, and snow all combined to prevent its prompt return. Several miles of riding, and fifteen miles of skating over untried ice, got the battery home and enabled me to visit my patients for that day.

Servant announced my three riding-horses had "distemper." My list showed several important cases for the day. Ground covered six or eight inches with ice, snow, and slush. I *thought* about sixteen miles of walking would pull me through the day, and it did; also *thought* what a good time the famous specialists in the big cities must have in their warm and dry offices; this weighed upon my brain, as my feet grew heavy from fatigue and wet boots.

Having just dined, being very tired, and having nothing to do, I determined to rest for a day. Two urgent calls came. I drove to see one, had to cut a very nervous lady, which detained me; could see the other before dark, which was important, provided I could cross the river. Driving rapidly to the river, the boat was there, but at the bottom; *thinking* about "dry docks," "marine railways," and other luxuries common in great cities, a piece of rope, a stake, and two round fence-logs, with the help of a "small boy," got the boat on shore, turned her over to get rid of the water, launched her, crossed the river, walked two or more miles, saw my patient, got home after dark, and after supper I was called out again.

From hot weather, and being run down from overwork, I went to the city to consult a specialist. He told me, what was to be expected, no royal road to health—doctors, like their horses, should rest when weary. In my rural simplicity I *thought* he had received a circular of some new elixir (indorsed, according to the code, old or new, I cared not which, with a thousand good names), a teaspoonful of which would heal my ills. He treated me, "a country doctor," as I would treat a horse, or ox, or ass. He told me to *rest* when I was *tired*. This was Monday, and I determined to rest the next week. But I had an unusually hard week's work. Things culminated Saturday. I was very busy all day and went to bed exhausted about twelve o'clock, and was called up about one. Nothing but the results of a free fight: case one, cut hand, plastered it; case two, triceps gashed with a knife, sewed it up; case three, throat cut, sewed it up—wanted to consult on this case, no doctor near and no time to hunt for one; all well in two days, however.

Went to bed to get some rest, Sunday, 3.30 P.M., after my usual morning work. *Thinking* of many accidents possible to my surgical cases of the preceding night. At 4 P.M. called up, urgent message, accident at a hotel five miles away on the bay. Here was need for again thinking. Three cases (two of them serious) on hand, in addition to an already full list, mentally and physically exhausted neither time to eat nor sleep, no professional brother to help me. Dressing quickly, I mounted my "colt;" the groom said something about "on grass." You city doctors, with well-trained and oat-fed horses, may not know what the import of this brief sentence was? Fond of horses from youth up, every mile of my ride was painful; I was anxious to go fast, so was the colt. The day was hot, and "on grass" meant the loss of the colt if he was allowed to go fast. Got to the hotel—patient not seriously hurt—in fifty-five minutes after I was called.

Reached home, colt "tired in front," self too exhausted for another ten-mile ride; had to go back to the same place to see another case. A storm was impending; I immediately *thought* of a large sailboat, and three sailors to man her, and rode my tired beast to the place. Got the boat and men, who wanted to see the "fun," as they expressed it. The storm broke, the "fun" came, the boat went. Emerson tells of "the joys of eventful life" in a few minutes! We "scudded" several miles, made a good landing, I saw my patient, and returned home.

There are many thousand "country doctors" working out daily just such exasperating troubles. They risk limb, health, and life coming and going, and are equal, as a rule, to every emergency. Minds and bodies are constantly trained and developed. Julian with his fourteen hundred ships on wheels, Napoleon with his six hundred vessels, De Lesseps and Eads, all had men with whom they could consult and advise when in distress over transportation problems, and somebody paid the bills. The men of whom I write, in their loneliness and desolation, solve such problems themselves, and if they err in the instant thought; pay the penalty with their lives. Thinking is the country doctor's "hobby," and when at times he can't ride his horse, he always rides his hobby. Day and night he thinks, the "muddy boots" he wears do not cloud his brain, any more than the polished boots of city doctors brighten theirs. RUSTICUS.

[Well done, Rusticus. The man who braves so much to see his patients generally does something for them when he gets there.—ED.]

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 2 to January 8, 1887.

RAYMOND, H. I., First Lieutenant and Assistant Surgeon. Ordered for duty at Presidio of San Francisco, Cal. S. O. 127, Department of California, December 29, 1886.

IVES, F. J., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, with permission to apply for twenty-three days' extension. S. O. 1, Department of the Platte, January 3, 1887.

THE INTERNATIONAL HOMŒOPATHIC MEDICAL CONGRESS, which was to have been held this year at Brussels, has been postponed to the year 1889, and will then meet in Paris. The reason of the postponement seems to have been that a fair attendance of members could not be secured and not enough papers were promised. The Belgian homœopaths do not regard this failure as a sign that their exclusive system is losing its adherents, but throw all the blame on their English brethren, whom they regard as traitors to the cause.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 8, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	6
Scarlet fever	44	9
Cerebro-spinal meningitis	5	5
Measles	497	65
Diphtheria	152	52
Small-pox	0	0
Yellow fever	0	0

A CASE OF LONG TOLERANCE.—A writer in the *Quarterly Journal of Inebriety*, for October, 1886, reports the case of a merchant, forty-two years of age, in active life, who had been a paroxysmal inebriate for ten years. When the drink paroxysm came on he acted so wildly that both his moneyed interests and that of his friends suffered greatly. It was found that moderate narcotism from chloral and morphia kept him in bed and cut short the paroxysm. It was customary to get a two-ounce mixture of chloral, morphia, and bromide, giving the officinal dose until he became stupid or sleepy. On this occasion the usual bottle was procured, and given in regular doses every ten minutes, without any results; a second was given, then a third one, after which the patient went to sleep. His son, returning a few hours after, noticing the heavy, unnatural sleep, sent for assistance, and the physician who came found that the patient had taken in three hours about nine grains of morphia, three hundred and twenty grains of chloral, and over an ounce of bromide of sodium. Four hours had passed since the last dose had been taken, and, excepting a heavy stupor and general pallor, no alarming symptoms were present. It was decided to pursue an expectant plan, and watch the case rather than attempt any active antidotal treatment. For the next ten hours he remained in a general stupor, from which he could be easily roused, and was rational, but quickly relapsed into a quiet, heavy slumber. This stupor continued for four days, gradually growing less, with longer waking periods. Then he rode out, but was drowsy and heavy for a week more. The drink paroxysm had passed, and he returned to his usual work and health, not conscious of any unusual drug-taking. This person was a delicate, nervous man, apparently very sensitive to all the surroundings, and with no indications of any peculiar organization or debility.

IDIOSYNCRASY AS REGARDS TANNIC ACID.—Dr. J. M. Williamson relates, in the *Practitioner*, a curious case of idiosyncrasy with respect to tannic acid. The patient suffered from severe dyspnœa whenever the drug was exhibited. The writer thinks that in an anæmic subject, as was his patient, the process of converting tannic acid into gallic acid may be in some way retarded.

GIVING MEDICINES IN CAPSULES.—In the *Southern Practitioner* for September a very practical fact is mentioned concerning capsules as vehicles for unpleasant medicines. When any form of alcohol is taken with them they are rendered insoluble. Tannic acid also precipitates the gelatine covering and renders it insoluble. When the stomach is inflamed and irritable, following excess in the use of spirits, medicines should not be given in capsules. Neither chloral nor morphia should ever be given in this form to inebriates; it is useless.

A DIFFERENCE.—The difference between a hill and a pill is that one is hard to get up and the other hard to get down.—*Ex.*

THE CURABILITY OF CANCER BY OPERATION.[1]

BY GEORGE F. SHRADY, M.D.,

NEW YORK.

THE question whether or not cancer is curable by operation is one of the greatest interest to the practitioner who may be brought face to face with the answer to it. Every one who is affected with the disease is nerved with a desperate hope that an affirmative decision may be reached. The popular mind is educated to the belief that a positive diagnosis is synonymous with certain death sooner or later. Unfortunately the fears in the latter direction are quite well grounded by examples of recurrence of the disease, which are relatively frequent and correspondingly impressive. The burden of inspiring hope too often rests mainly on the consultant. With a view of aiding each other in arriving at conclusions in given cases it behooves us occasionally to compare notes and exchange experiences. We may not be able to tell other than the old story, but we may perchance point it with a new moral.

In the attempt to discuss in a general way the advisability of operation for the cure of cancer, we shall find it of the first importance to review such facts as may bear upon a local or constitutional origin of the disease. The proper conclusions from one standpoint or the other are obviously of the greatest moment in recommending any radical line of treatment.

In the way of outlining the argument in favor of the curability of cancer by operation, I shall endeavor to prove that the disease has a local origin, and is therefore removable, and that the constitution becomes affected only secondarily by a more or less wide-spread dissemination of original cancer-germs.

If with microscope in hand we should be prepared to anticipate the first departure of a given tissue from a healthy standard to a cancerous disposition, we should find at one point merely an abnormal and atypical cell-proliferation. The cells become closely packed together into irregular alveolar spaces in a stroma of more or less developed connective tissue. So much may serve as a condensed description of the well-recognized anatomical characters of carcinoma.

It may be noted here as a significant fact that such growths are rarely if ever multiple in character. The histogenetic rule is for the disease to commence at one point, and thence spread, at first along lymphatics, into the neighboring glands, and afterward, through the medium of the blood-vessels, into more remote parts.

The growth is governed by laws of its own, follows a regular course, and, as a rule, propagates its particular kind of cell to secondarily infected parts. It having once made a start it is easy to trace the effects of the progressive march of the disease. Even when disseminated into distant parts there is no proof against the working of the law of transmission of proliferating cells from the original growth. We know that these cells are the cause of infection, and that when once formed they have an inherent property of multiplying themselves in the tissues in which they find a lodgement.

Why they are formed, and why they act thus, no one knows. The study of the phenomena is, however, the most fascinating one in the whole range of pathology, and has naturally interested the brightest minds, and been productive of the most ingenious theories. A reference to the most generally accepted one, that of Cohnheim, relating to the embryonal origin of cancer, will perhaps aid us in accounting for the primarily local character of the disease. That observer maintains that certain embryonic cells from the epiblast remain latent in the tissues of the body until some conditions of irritation or other local change provoke them to activity and growth. In the absence of a better explanation, this, it seems to me, is the most plausible that can be offered, inasmuch as the growth of cancer has such a striking resemblance to the methods of primary cell-development in the embryo.

According to Mr. Savory, the lower the grade of embryonic tissue, the greater its reproductive power and the more enduring is its vital force. Certain it is that the cancer-cell is of this type, and has a remarkable inherent power of multiplying itself as such. Furthermore, beyond this early stage the typical cancer-cell never goes. He believes that what is wanting is to be found in the nature and vital attributes of the formless protoplasm out of which the cells are produced.

Mr. Hubert Snow puts it in another way.[1] He says: "The phenomena of malignancy results from conditions which irritate normal protoplasm, which cause it to proliferate abnormally, and to assume a quasi-independent parasitic vitality. These conditions may be mechanical, but in a much larger proportion they are neurotic." All of which may be interpreted to mean that the nature of cancer is to be cancerous.

Mr. Savory's view regarding low-grade cells and proportionate proliferating power makes plausible the reason why the congenital tumors as such do not, as a rule, become malignant, as the higher and more varied the development of a growth the less its inherent vitality.

We might go on with this part of the subject indefinitely, but to no better purpose than of coming to our present standpoint in the acknowledgment of the principle of malignancy locally manifested in a definite and well-recognized manner.

In spite of all the theories of cell-origin, vital law, and actual being, we still mutely stand upon the barren edge of fact, and look upon the mysteries of creation around and about us in impotent wonder. Formative protoplasm, after all, means nothing but a name. It comes as it goes. We theorize in a circle. From the how to the what of the unknowable is sharply drawn the dead line of human thought. Beyond it is an emptiness of understanding and a despair of argument. But whatever may be considered to be the origin of cancer, the first manifestation of its presence to the microscope is the atypical cell-growth, confined to a particular locality, and spreading thus in a regular and progressive way to tissues in the immediate neighborhood. This is an anatomical fact, whatever way we may explain it. Nothing more than mere theory has been brought forward in the attempt to controvert it, and we must accept the microscopical demonstrations accordingly.

[1] Read before the Practitioners' Society of New York, January 7, 1887.

[1] Lancet, October 23, 1886.

If we study the clinical aspects of carcinoma we must confess that the weight of the argument is also on the side of the local origin of the disease.

We have seen that cancer begins as an isolated growth in a particular tissue, and progresses thence by a transfer of its proliferating cells into neighboring parts. But there is something in the predisposition of certain organs to be attacked which we likewise do not yet understand. Cancer is mostly a disease of local degeneration, and most frequently attacks organs—for instance, the breast and uterus—while they are undergoing retrograde metamorphosis. But this will not explain all the cases, as cancer sometimes occurs in these organs before such changes have taken place, and while they are in an active state of evolution. We may, for the sake of the argument, allow that in some persons the degenerative changes necessary for cancerous invasion take place earlier than in others. But it would hardly be fair in this respect to compare the organs of a youth with those of a septuagenarian. Still, there is a great preponderance in favor of the original proposition. At all events, the predisposition appears to be purely local in character.

Then we are told by Virchow and others that the determining cause is irritation. This does not cover as much of explanation as we might wish for in a perfectly tenable theory. It is, doubtless, one of the factors, but not always the main one. What woman has not received a bruise of the breast? how many of them are free from lacerations of the cervix uteri? how large a number of men irritate their lips with clay-pipe stems, or have their tongues scraping against decayed teeth? And yet a comparatively small number of these have cancer. There must be something besides mere irritation to cause a face-wart in one case to stand its ground against the constant knicking and scraping of the razor, and in another case, without apparent cause, to degenerate into an epithelioma, or an adenoma—in one instance to be carried a lifetime, and in another to take on without warning the irregular cell-growth of malignancy. Paget refers to three examples of scirrhus of the breast which occurred apart from, and independently of, chronic mammary tumors situated in the same organs, and I have seen the same thing in a case of chronic mammary abscess.

There would be some comfort in being able to explain, on the hypothesis of local origin, how and why certain organs are attacked, to the exclusion of others apparently similarly exposed, but we must, obviously, for the present be content with the mere knowledge of the fact.

A strong argument in favor of a local origin is this very circumstance that certain organs are always attacked, to the exclusion of others. We have the uterus and breast in the female, while in the opposite sex we have the skin and digestive organs principally attacked. On the other hand, the spinal cord, tendons, tonsils, pharynx, liver, lungs, and prostate gland are rarely involved primarily.

Again, we notice that one organ becomes diseased, and its companion escapes. Organs also of the same structure—for instance, the parotid and submaxillary glands—are not similarly affected; the first is, as a rule, attacked primarily, the latter secondarily.

We can, perhaps, account for this condition of things by assuming that those organs most liable to malignant disease are those in which the embryonic protoplasm, in greater or less quantity, is deposited. If we go thus far we can conclude that cancer should not occur primarily in any organ in which this formative material does not already exist. But, of course, regarding this point we can demonstrate nothing.

The more we study the question of the origin of cancer the more we must take into account complex exciting causes, such as mental influences, reflex disturbances, and the milder forms of derangement that are manifested during the too rapid growth or too rapid degeneration of an organ. But we still have to account for the apparent immunity of the other important organs under all the foregoing conditions.

Interesting as is this part of our study we must pass on to consider other points in favor of local origin. Let us cursorily review some clinical phenomena. These may be stated dogmatically for the sake of brevity.

The clinical facts of cancer cannot be explained by regarding it as an affection of the blood, either primarily or secondarily. The general system is never affected in any recognizable way before the local disease has shown itself. The cancer may spread, but always from a given root. The blood is doubtless the fertilizing fluid, but nothing more.

The disease prefers to extend into adjacent tissue rather than to another similar organ. Take, for example, the history of cancer of the breast.

The disease manifests different degrees of malignancy in different situations. Scirrhus of the breast behaves differently from epithelioma of the lip.

Hereditary influences cannot militate against this doctrine of local origin; if so, they should be more frequently met with than in the proportion of one to six. Besides, is it not possible to inherit local as well as constitutional tendencies? Examples of such are too numerous to mention.

While speaking of heredity it is well to bear in mind that it is an exception for more than one member of a family to become the victim of cancer.

While this is a comforting outlook in one direction, it is far from it in another. If heredity has so little influence, the inference is that other causes, of which we are still in ignorance, operate indiscriminately upon all the human family. In fact, statistics have shown that no one can be sure to escape cancer until he has passed the age for its occurrence, and when his vital machinery is actually worn out. In other words, he can never positively be considered fortunate in respect to cancer until he is dead.

The tendency to recur can be based as much on the local as the constitutional theory. Recurrence presupposes origin. The origin is always local, and the recurrence, whenever the attempt has been made to prove it, has been found due to a systematic and progressive distribution of cell-growth into adjacent parts. The occurrence of cachexia or constitutional disturbance is explainable on a similar supposition. The constitutional infection may be said to be due to a multiplication in different organs of the original growth. The cachexia is evidently caused by the involvement of one or more vital organs.

Finally, what is certainly an unanswerable argument in favor of local origin is the cure of the disease by the removal of the local growth. Conversely, because the disease has a local habitation, operative procedure is advisable. It is with the view of establishing such a principle of treatment in all possible cases that this paper was principally written.

It has not been my purpose to give other than a summary of facts which have been accumulated by personal experience, and as the result of the study of a large number of statistics collected from various sources. Whether the conclusions are legitimate or not, the points thus presented may be of some interest to others, who, like myself, may need some data on which to found an opinion upon cases as they ordinarily present themselves for advice.

The statistics regarding the results of operations have never been collected on a sufficiently large scale.

This has yet to be done before the question as to the advisability of operation in the general run of cases can be definitely settled. No attempt in a paper of this length can be made to give more than an outline of studies in this direction. Such will, perhaps, serve our purpose in presenting a better ratio of recoveries after the use of the knife than is usually believed to be possible.

In estimating the value of operations for cancer, we must take into account the average duration of the disease in a particular organ and when left to itself. Paget, in 139 cases of scirrhus of the breast, gives the duration of life in 75 cases not operated upon as forty-eight months, while in the remaining 64, which had one or more operations, the life-average was over fifty-two months. Sibley, in 84 cases, makes the averages thirty-two months in cases not operated upon and fifty-two months when excision was practised. Baker counts forty-three months against fifty-five months. The longest duration of life in cases not operated upon was twelve years; in those operated upon a little beyond eighteen years. Satterthwaite [1] shows, by his statistics, that operations lengthen life to the extent of more than eleven months on an average. His figures are 35.7 months without operation against 46.8 months with operation.

S. W. Gross credits the prolongation of life in favor of operations one year. The same observer, in an analysis of 524 operations, says there were living and well three years after the last excision of the growths 1 in 9.19; and ten years after, 1 in 5.7. Recurrence was prevented in 32.30 out of every 100 cases.[2]

Dr. Willard Parker believed in the benefit of operations in selected cases In a paper read before the Medical Journal Association in September, 1873,[3] he reports 14 cases of cure by excision, the patients being in good health at the end of periods varying from three to twenty-seven years.

Nussbaum, of Munich, is of the same opinion, and affirms [4] that those patients operated upon live decidedly longer than those who have not submitted to such treatment.

Dr. Oldekop [5] publishes an extended report of 229 cases of excision treated in Esmarch's clinic, with 23 recoveries. The average duration of life in cases operated upon was 45.1 months, against 22.6 months when the disease took its ordinary course.

From an examination of the records of the Vienna Pathological Institute, Drs. Török and Wittelshöfer [6] are enabled to say that of 184 autopsies on cancerous papatients operated upon, only 105 had metastatic deposits, and of 182 without operation only 40 were free from secondary carcinoma.

Statistics might be multiplied to prove the chances of radical cure in cases which have been treated by the knife, and of the certainty of prolonging life by excision of cancerous growths. In fact, even better results are noted in other forms of cancer, as, for instance, epithelioma of the lip, of which nearly one-half the patients are cured. We have, however, collected our figures mainly from cases of cancer of the breast, as they are the most common of all malignant growths, and may serve as the type of the others. What is true of a part may be equally so of the whole.

We might multiply cases to prove the utility of operation, even on the basis of the severe test of Paget, an entire immunity from the disease for ten years and over. I can recall two such in my own experience, one being alive and well when last heard from—thirteen years after an operation—and the other dying of apoplexy eleven years and three months after the last operation. In the latter case three operations were performed, at varying periods, for the removal of recurrent growths.

Dr. Weir [7] reports a case in which the right breast was amputated by Dr. James R. Wood in 1856. In 1867 Dr. Post amputated the left breast; in 1873 Dr. Weir removed a recurrent growth from the right side, and again in 1877 and 1880, the patient finally dying of the disease in 1881. This covers a period of twenty-five years.

Dr. Austin Flint, in a discussion on the subject before the New York Academy of Medicine, referred to a case operated on by Dr. Frank H. Hamilton which survived the operation twenty years, and that of another patient, also treated by Dr. Hamilton, who was living ten years after the extirpation of a cancerous breast.

Dr. Daniel Lewis also related to me a case which, if I recollect right, survived an operation ten years.

Dr. C. Deadrick,[1] of Knoxville, Tenn., reports a case which also proves in a striking manner the value of repeated operations for recurrent growths. A lady, aged fifty-eight, was first operated upon in May, 1878, for a cancer of the breast and axilla, of two years' duration; again in July and August, 1878, and in May, 1879; she remained well until August, 1886, when she died of marasmus. The patient was free from the disease over seven years, and her life was certainly prolonged for that period

The question of figures is not always of the first importance in estimating the value of any particular treatment, or of forming opinions as to results in individual cases. Many other circumstances have also to be taken into consideration. In estimating the relative importance of these, the general impression of the study of all points involved must be taken into account. As a contribution in such a direction, the opinions herein expressed are duly offered.

Every surgeon meets with such cases of cure by the knife, and I am convinced that if he could follow up the subsequent history of his hospital and private patients he could add greatly to his favorable statistics. It matters not if the disease does recur, it can prove scarcely more than that the growth was not thoroughly extirpated in the first place. This may be no fault of the operator, but may be due oftener to the aggressive infiltrating tendency of the disease. Cancer has no cyst wall; all the surrounding tissues are open to invasion, and oftentimes we find cell-growth remote from the original focus, and in such apparently healthy tissue that the microscope is alone able to decide the point. We often see this in cases of mammary carcinoma, especially in adipose subjects.

This, pathologically speaking, has a very important bearing upon the extent of the field of operation in given cases. I am firmly convinced that operations, as a rule, are not radical enough to insure a complete and thorough removal of the disease. The surgeon, being first sure of his diagnosis, should never undertake an operation unless he is also reasonably certain of the limits of the disease and is confident of his ability to cope with every emergency that may arise. There should be no doubts in his mind that every vestige of the disease has been removed. The size of the wound and the number of vessels involved are secondary considerations. For instance, it is not enough to remove a breast, but it is also necessary to carefully dissect the axilla for diseased glands, removing the latter even from the sheaths of the larger vessels. This is the only way to be on the safe side against recurrence. It goes without the saying, also, that the earlier an operation is performed the better the chance of thoroughly extirpating the disease. The operation is less formidable, the wound is smaller, and the shock is less. In doubtful cases I am inclined to give the patient the benefit of an operation, explorative at least, rather than trust to the chances of the disease spreading beyond the reach of the knife.

The time of the performance of an operation is of the greatest importance. One reason why operations so often fail is that the cases requiring them come to the surgeon too late. Statistics show that the patients operated on early always do the best and are least liable to recurrence of the disease. This fact cannot be too forcibly emphasized.

Again, it is better that we run a chance of recurrence than that we take the other alternative of allowing the

[1] MEDICAL RECORD, vol. xxx., p. 345.

disease to get beyond us and kill the patient, for recurrence generally means slower growth and less pain.

But even taking everything into consideration, and allowing that the odds are against us, we should not be discouraged in giving our patients their only chance. Practically, the operation comes to that. Otherwise our patients must voluntarily resign themselves to the inevitable.

But even if the rule of recurrence obtains, there are so many examples of final cure after repeated operations that the faith in the knife should not be too easily shaken. It is sometimes a question which should wear out the sooner, the blade or the disease. There are instances of cure after five, six, and seven operations. If need be, we should say "seventy times seven," rather than grow weary in well-doing.

I am also led to believe that a new encouragement is open for surgeons in the different methods of operating at present as compared with those of former days. We can perchance commence to build fresh statistics with better results in clean and rapidly healing wounds, and in the elimination of many of the old-fashioned elements of wound treatment, which of themselves either militated against recovery or directly invited recurrence. The time may yet come when we shall ultimately make as brilliant a record for the operative treatment of cancer as for other similar procedures which heretofore were considered to be impossibilities. At least we must be encouraged to try to the bitter end, and this may perhaps be the new moral to the old story.

If any practitioner needs any special urging in this direction, let him contrast his experience in those cases which are operated upon with those which are not. In the former, there is at least relief from mental anxiety, from pain and other suffering, and life, which before was a burden, is made a happiness. In the latter, the inevitable issue is awaited with the grimness of despair—the patient undergoing tortures of mind and body too horrible to contemplate—the sole relief being in that hopeless slavery to opiates which drops its chains only at the portal of the grave.

In summarizing our conclusions the following propositions are offered:

1. Cancer is essentially a local disease, and can be cured by operation in spite of recurrence.
2. Operation, when it does not cure, prolongs life and diminishes the total amount of suffering.
3. Operations should be repeated as often as there is any chance of entirely removing recurrent growths.
4. The earlier and the more thoroughly the operation is performed the better.
5. The disease, when it recurs, is generally of a milder type than that of the original growth, less painful and less exhausting.
6. Antiseptic surgery makes more radical operations possible, with better ultimate results, than formerly obtained.

247 Lexington Avenue, New York.

A Dangerous Operation—for the Doctor.—Dr. Souchon (*Texas Medical Journal*) related a case of abscess of the axilla which was incised while the patient was only partially under the influence of the chloroform As the knife penetrated the flesh, the patient sprang to his feet, rushed at the case of instruments, which was near by, and had half opened a drawer and was about seizing an instrument, when one of the students bravely caught him. He very soon quieted down. The next day he said that he had just come from a grinding on a sugar plantation where a number of Chinese were employed; that he was always quarrelling with them, and that, as he was going under chloroform, the students around him became gradually transformed, in his mind, into Chinese; and that as the knife penetrated him, though he felt no pain, he was satisfied it was one of the Chinamen who had stabbed him. Hence the rush he made to what he thought was his armory, for a weapon to defend himself.

ON A SATISFACTORY METHOD OF EARLY DIAGNOSING AN INTRA-PERITONEAL RUPTURE OF THE BLADDER.[1]

By ROBERT F. WEIR, M.D.,

SURGEON TO THE NEW YORK HOSPITAL; PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS.

The following case is of interest, as it demonstrates very happily the availability of a recent surgical device in the solution, in certain injuries, of the existence or non-existence of a rupture of the bladder.

Joseph K——, a young man, aged eighteen, was brought into my wards, at the New York Hospital, December 18, 1886, having been crushed by a very heavy packing-box falling off a cart upon him, while helping in the process of unloading. The weight came upon the lower part of the abdomen and upon the right thigh. He was seen by me some six hours after the accident. He had passed in the meanwhile four ounces of slightly bloody urine. He complained of tenderness over the pubis, and there was above this bone an area of dulness reaching upward a distance of over an inch and a half. The belly-walls were rigid, and slight tympanites was observed. Inability to raise the right thigh was also present, and movements imparted to the limb gave rise occasionally to crepitus. No shortening on measurement, however, was detected, and no fracture in the femur was made out. By examination per rectum a swelling over the middle of the ascending ramus of ischium was found, and pressure over the trochanter developed the existence of a fracture at the site of this tumefaction. He passed urine on being requested, and with but moderate pain. Nearly four ounces were evacuated, and it was distinctly bloody. On introducing a silver catheter it passed in up to the eyes, and drew off no additional fluid; but it gave a roughened sensation when about half withdrawn, and on reaching the anterior portion of the bladder about a teaspoonful of still more deeply tinged urine flowed out. He was not suffering at all from shock.

The question arose naturally as to whether a rupture of the bladder had not taken place. From the supra-pubic dulness it was inferred that if such had occurred it was probably extra-peritoneal. This point was then determined by the insertion of an aspirator needle, which evacuated a couple of drachms of fluid dark blood and its point impinged readily on the fractured bone.

The decision as to whether an intra-peritoneal rupture was present, was a more difficult one to arrive at. This could be accomplished expectantly by waiting for further symptoms; but, obviously, the earlier surgical help could be rendered in such conditions the better the chance of recovery to the patient. Only two procedures seemed available therefore, viz., digital exploration by a perineal incision,[2] or by opening into the abdominal cavity. Rather than resort to either of these I thought of using the test of distention of the bladder, as has been employed in the recently improved supra-pubic opening of the bladder for calculus, tumors, etc.

Accordingly, two hours later, the abdominal tenderness having increased, the patient was etherized and a rubber catheter first inserted into the bladder, and then Peterson's rubber-bag [3] passed into the rectum and distended with seven and a half ounces of warm water. After this had been done, and after the line of supra-pubic flatness, now slightly augumented, had been outlined by a colored pencil, seven and a half ounces of a carbolic-acid solution—one to one hundred—were slowly introduced into the bladder. When six ounces had been passed in, the contour of the bladder could be felt above the line of blood extravasation, and the additional quantity of fluid served only to make this more positive, especially so

---

[1] Read at a meeting of the Practitioners' Society, held January 7, 1887.

[2] See an article on Rupture of the Bladder treated successfully by Perineal and Hypogastric Incision and Drainage, Medical Record, March 29, 1884.

[3] The bag had been encircled by a netting of silk to prevent over-distention, as suggested by me in a recent paper on supra-pubic cystotomy, Medica News, December 4, 1886.

on the lateral aspect of the distended viscus. The injected fluid was then allowed to flow from the bladder and measured, and found to correspond with the quantity forced in. The demonstration was perfect, not only as to the possibility of an intra-parietal, but also, from the non-increase in the line of dulness over the pubis, as to an extra-peritoneal laceration, and the rectal bag was thereupon also emptied and withdrawn, and the patient saved from any surgical interference of a more heroic character. A body bandage was applied, and in the course of forty-eight hours all traces of blood, even microscopically, disappeared from the urine. The source of the blood was evidently from the contusion to the lower part or to the neck of the bladder, by the inwardly projecting fragments of the fractured bones, which could be felt to tilt markedly toward that organ on strong manipulation of thigh.

In carrying out this test it will be observed that the precautions of not distending too much either the rectum or bladder were carefully observed. Such are necessary, as has been shown by me in some remarks lately published on this subject,[1] in which five cases of rupture of the bladder by surgical distention are reported. To obviate this risk a rectal dilator, which can only be distended to a circumference of seven and a half or eight inches should be used, and not more than seven to eight ounces of antiseptic fluid passed into the bladder. Should more vesical distention be required, any augmentation of the injection must be made very slowly and cautiously.

The brilliant results obtained by Sir William MacCormac in two intra-peritoneal ruptures of the bladder, by laparotomy and suture of the laceration, published in the *Lancet* of December 11, 1886, conclude with the advice that in cases of doubt an exploratory incision into the abdomen would be justifiable to secure the accuracy of diagnosis and promptness of action desirable in these important cases. It is believed, therefore, that this simpler method may prove of decided advantage in the uncertainties that so often attend vesical ruptures.

IS DIVISION OF THE MEATUS URINARIUS A SIMPLE MATTER TO THE PATIENT?

By W. H. BENNETT, M.D.,

BROOKLYN, N. Y.

As this question is an important one, and has claimed the attention of many eminent surgeons, I do not think any apology is necessary for again bringing it to the notice of the profession, particularly when we take into consideration the fact that there seems to have been with some men, of late years, a perfect craze for doing this operation (?), and seemingly in many cases without any well-defined idea of what is to be accomplished thereby.

It is evident to anyone at the first glance that, in a given case of stricture of the urethra requiring division or divulsion, it may be necessary, in order to introduce an instrument for either purpose larger than the calibre of the canal at the meatus, to enlarge the orifice in some way, and there can be no doubt that there are quite a number of cases where such a procedure is justifiable. Again, in some cases of obstinate discharge from the urethra due to gonorrhœa, where the meatus is contracted or congenitally small, it may be good treatment to enlarge it. I think I have seen good results from such operations. But to my mind the meatus is cut far oftener, and to a much greater extent, than there is any occasion for, and as a result of this there is, I believe (and I propose to try to demonstrate it), a gradual loss of elasticity of the urethra, loss of sexual desire, and also loss of contractile power of the bladder—atony, which there should be an attempt to obviate, whenever it is possible, by restoring the meatus to its normal dimensions.

As one's ideas are so often apparently misconstrued, I wish, if possible, to make myself fairly understood at the outset. I do *not* say there are no cases requiring division of the meatus, nor do I affirm that all cases of loss of sexual power are due to a slit meatus, nor that it is possible to properly repair every injured meatus, nor that all meatus should be repaired. I *do* protest against the routine practice of enlarging the meatus, and I *do* say that, the operation having been done, I am led to believe that, generally, a certain loss of function will follow, unless the orifice be early narrowed down to its normal size, which loss of function I think may in many cases be partially restored by repairing the injury done the meatus, even at a late date.

Considering the matter in detail we may speak of the male urethra as an elastic tube with a lining of mucous membrane, and an outer coat of erectile and muscular tissues. It is not necessary here to enter more minutely into its anatomy. It is the outlet to the bladder, and its functions are to transmit the urine and semen. In the normal state its calibre varies; it is narrowest at the *meatus*, then dilates into the fossa navicularis, behind which it is again somewhat contracted, and again it dilates at the bulb to become in turn much narrower immediately behind this point where it passes through the triangular ligament, when once more it enlarges as it passes through the prostate forming the sinus pocularis. Behind each contraction it will be seen there is a dilatation, and these several variations in the diameter of the canal serve an important purpose.

In the act of urination the bladder contracts, the sphincter relaxes, the urine is driven along the normal urethra, meeting with only slight obstruction at each point of narrowing and filling each enlargement of the canal, till the meatus is reached, where the size of the current is so narrowed that the volume of fluid is obstructed and dammed back in sufficient quantity to forcibly distend the whole elastic tube, while, the pressure of the contracting bladder continuing, the urine escapes in a smooth and continuous stream. When the bladder has contracted down to its utmost, then the accelerator urinæ and other accessory perineal muscles may be called into play, by the voluntary contraction of which the greater part of the urine that remains can be quickly and forcibly expelled; or the urethra, being allowed to contract on its contents more slowly after the sphincter is closed, forces out the last few drops. There is no dribbling, because there is not from the commencement of the act to its completion any intermission in the expulsive force, unless it be due to the voluntary contraction of the compressor, or "cut-off" muscles; for though the bladder ceases to act before the urine has all escaped from the urethra the latter organ continues to do so, with much less power of course, but with sufficient to expel its contents in a continuous if less forcible stream. The narrow meatus, like the nozzle of a hose, not only increases the pressure from within and causes an acceleration of the current, but it prevents the immediate withdrawal of the expulsive force when the bladder-pressure ceases. The function of the meatus is therefore apparent, and so also, it seems to me, is that of the several normal contractions and dilatations within the canal itself, which I believe act mainly in preventing the detrusor muscle, when the vesical sphincter is relaxed, from too suddenly and forcibly filling the whole urethra, at a gush, as it were. In other words, they serve to lessen the shock and prevent pathological changes therefrom. The urethra was intended to last a man his lifetime, and nature has therefore done her best to protect it from injury and preserve it to him intact.

Now, supposing the meatus to be divided to the extent only of making it correspond in diameter to that of the spongy portion of the canal immediately behind the fossa navicularis, what is the result? Instead of

[1] Loc. cit. supra.

obstructing and narrowing the outflowing stream and thus insuring smoothness with increased force of propulsion, it allows of the escape of the urine readily, in a stream the diameter of which corresponds to that of the now narrowest (membranous) part of the urethra, and with the propulsive force greatly diminished. There is no resisting force to speak of opposed to the contracting bladder, certainly none worth taking into account, anterior to the triangular ligament, and consequently no considerable distention of the tube with subsequent contraction, no exercise of the organ, as its muscular elements lose their tone for want of proper use. At first, when urination is finished so far as the bladder is concerned, the elasticity of the canal may probably be sufficient to expel all the urine therein contained at once, but in time its contractility is lost to a great extent, and the moment the bladder ceases to exert its force a few drops of urine dribble away from the incomplete contraction of the accelerator muscles, and then, after an interval, probably after the penis is replaced, a few drops more trickle away from the contraction of the spongy urethra itself. And it is not the urethra alone that suffers, but the muscular coat of the bladder also, not being called upon to act with its accustomed vigor, loses in turn its tone—degenerates, to a certain degree, like any other muscle imperfectly or only passively exercised.

If a still greater division of the meatus have been practised the orifice of the urethra is converted into a funnel-shaped opening, there is now no resistance here to the escaping stream of urine, and the condition of affairs already mentioned occurs sooner and is more marked.

The fact must not be lost sight of that the accelerator urinæ, transversus perinei, levator ani, and probably even the erector penis, all being generally instinctively and almost involuntarily called into play at the end of the normal act of urination, to quicken the process, are, when the meatus is divided, less and less used and these muscles also degenerate, or at least lose tone. As a consequence of this, during the sexual act erection is incomplete and short-lived, and intercourse is unsatisfactory. There is also a loss of sexual desire as well as of virility, partially owing to the causes already mentioned, and, in a measure, due to the fact that the mucous membrane of the lips of the incised meatus, being exposed, loses its exquisite sensitiveness; besides, the frænum generally being injured, it no longer tightly closes and pulls down the lips of the meatus, thereby elevating the corona of the glans and causing both these parts to come in closer contact with the vaginal walls during coition.

Many men in the prime of life and apparently full of vigor have come to me with enlarged meatus and the mournful tale that they were losing their manhood. They could no longer satisfactorily perform the sexual act; perfect erections were impossible; they had no control over the discharge of semen, which generally occurred prematurely; they experienced no orgasm and they had, so to speak, lost all sexual desire. Most of these men had been guilty, no doubt, of excesses in eating, in drinking, and in venery; but thousands of others, with meatus intact, have abused themselves in every way to as great an extent, and yet they retain their sexual vigor. In some of these cases the condition of affairs may have been caused by the passage of sounds of large size, but many had never had an instrument used on them a dozen times, and in several the meatus had been cut because it was thought to be abnormally small, to hasten the cure of an obstinate clap.

What goes further than all theoretical reasoning to prove the force of my argument is the fact that I have narrowed the enlarged meatus in five cases, with the result of restoring the functions of the organs concerned in urination and copulation to almost the normal degree, and this after other methods of treatment had failed. In every one of these cases the act of urination was faulty; there was no force to the stream, nor could it be directed into a vessel or urinal without wetting the immediate surroundings, unless the lips of the orifice were pinched between the fingers. No effort on the part of the patients could hasten the flow unless the meatus were artificially narrowed, and there was always dribbling. But these were all selected cases. Only two had stricture; one at the region of the bulb, admitting No. 24 F.; the other at three and a half inches, admitting No. 26 F. In each the stricture was divided and six months afterward the meatus restored to what was considered to be about its normal size. Sound No. 27 F. can now (four months after narrowing the meatus) be passed readily on both patients.

The operation, if it may be dignified by such a title, is simple enough, but care and judgment are required in paring the edges and in passing the suture or sutures. I have generally introduced a sound a couple of numbers smaller than I had intended the meatus should admit when the wound had healed, and then pressing the lips together over this, have formed an idea of where I was to cut and where the sutures were to be introduced. The sutures may often with advantage be introduced first; one has generally been sufficient, a piece of court-plaster being carefully applied and held in position till it firmly adhered, after the suture was tied. It depends a great deal upon the extent of the enlargement as to how the operation for closing this should be done. If a considerable portion of the glans, as well as the meatus, have been divided (as I have often seen), then, after the opposed surfaces have been denuded the sutures should, I think, be passed as in the operation for closing a ruptured perineum. I have not operated on such a case. In using but a single suture I introduce the needle on one side at a point on a level with what constitutes the superior angle of the newly made wound when the raw surfaces are pressed together, and bring it out at a corresponding point on the other side; then I introduce it again a trifle above the lower angle of the wound, and carry it back through both lips and tie. I use a very fine needle and thread, the latter simply waxed. A bit of lint or cotton is left between the lips of the meatus, so that they cannot become glued together and force the urine between the cut surfaces at the first effort at micturition. Of course the patient is made to urinate just before the operation is commenced.

Now, if the results herein detailed *do* follow, and are caused by the division of the meatus, when are we justified in enlarging it? In my judgment, if a stricture be recent and amenable to treatment by dilatation at all, it is sufficient, unless the meatus be abnormally small, to dilate it (the stricture) to the extent of passing the largest sound that the meatus will admit. Of course a strictured meatus, or a congenitally small meatus, must be cut. To my mind there is no use in dilating a constricted urethra farther than can be done by stretching the meatus a number or two; if this will not suffice, division or divulsion is required; for if contraction again occurs sufficient to give rise to symptoms after such treatment, it would have done so more speedily and more surely had the dilatation been carried to a greater extent. The idea of overdistending strictures means so often irritation or inflammation that I cannot believe in it.

If a stricture be resilient or irritable, or if it has been often inflamed, there is no use in irritating it still more by the frequent passage of large sounds. It had better not be treated at all instrumentally, unless it be so narrow as to threaten or give rise to considerable trouble, until the operation of division or divulsion is practised; and after such an operation a sound of 24 to 26 F. will generally be found large enough to pass, even though the stricture have been divided up to 30 or 32 F.; for our object now is simply to separate the cut surfaces or torn tissues, and not to stretch or irritate them. In every case where the meatus has been enlarged, it should be restored again to as near its normal size as is possible within a reasonable period of time, unless there be some well-defined reason

why it should remain enlarged. It is an easy matter to again divide it if there should arise any occasion for doing so.

As to enlarging the meatus when but seemingly small in cases of obstinate clap, I can only say that while I have several times done this with great apparent benefit to the patient, in so far as speedily stopping the discharge and relieving the other symptoms, yet, on the other hand, I have seen dozens of cases, where the orifice was equally contracted congenitally, get perfectly well during an ordinary course of treatment, without any complications or sequelæ. Most certainly, in these cases, if the meatus have been cut, it should be afterward restored to the normal.

No. 188 Sixth Avenue.

FERMENTATION AS A PRACTICAL QUALITATIVE AND QUANTITATIVE TEST FOR SUGAR IN THE URINE.

By MAX EINHORN, M.D.,

NEW YORK.

In an article, "Die Gaehrungsprobe zum qualitativen Nachweis von Zucker im Harn," which appeared in Virchow's *Archiv* (Bd. 102, 1885), I showed that the fermentation test enables us to recognize one-tenth per cent. of sugar in the urine; and further that, by first boiling the urine, even one-twentieth per cent. might be recognized. Now, inasmuch as fermentation is not only the most exact, but also the *only* test for sugar in the urine, the desire of bringing it more into practical use seems to be justifiable. The object of this paper will be to simplify, as much as possible, the method of making the test, and to increase the value of it by enabling us to ascertain at the same time the approximate quantity of sugar.

Before proceeding with the proposed theme, I will give a literal translation of the method of carrying out the fermentation test, as it appeared in my original article:[1]

"The test apparatus for this purpose is a fermentation-tube, and the most convenient form is that which is described by Salkowski and Leube.[2] It is made of glass, and consists essentially of four parts: (*a*) a spherical reservoir, open at both ends; (*b*) a cylindrical tube, closed at its upper end; (*c*) a somewhat narrower tube, bent so as to connect (*a*) and (*b*); (*d*) a stand to support the other parts. A small piece (one gramme) of fresh commercial compressed yeast is thoroughly shaken in a test-tube with about ten cubic centimetres of the fluid to be examined, and the spherical reservoir is filled with the resulting mixture. By inclining the apparatus, the mixture easily finds its way through the connecting-tube into the cylinder, completely driving out and replacing the contained air. Owing to the atmospheric pressure exerted on the reservoir end of the connecting-tube, the fluid does not flow back, but remains in the cylinder and tube. A little mercury is now poured into the reservoir; it sinks into the connecting-tube, forcing the fluid which was in the latter back into the reservoir. The cylinder is now filled with the fluid to be tested, and is shut off from the air by means of the mercury. It is evident that if alcohol fermentation sets in, carbonic acid gas will be evolved, and, displacing the fluid in the upper part of the cylinder, will force it back into the reservoir. The apparatus is left undisturbed at a temperature of about 30 to 33° C. (86 to 92° F.) for twenty to twenty-four hours. The changed level of the fluid in the cylinder shows that the reaction has taken place. The upper part of the cylinder is filled with carbonic acid gas. To carry out the test as suggested by Salkowski-Leube, three of these fermentation-tubes are necessary. Of these, A[3] is filled with the mixture of yeast and normal urine, free from sugar; B with the mixture of yeast and the suspected fluid, and C with a mixture of yeast and a urine to which sugar has been added artificially. (C is used simply to test the efficacy of the yeast.) Now, should the fluid have been forced out of the upper part of the cylindrical tube B, and its place taken by gas while in A, there is only a small bubble at the summit of the tube; then B contains sugar. If this is not the case, *i.e.*, if B contains merely a gas bubble similar to the one in A, while C, on the other hand, is partly filled with gas, then, obviously, B contains no sugar.

Being familiar with this method of carrying out the fermentation test, let us examine the first point of our theme, which has for its object the simplification of the method. In the above description it was said that, after having filled the fermentation-tube with urine and yeast, mercury must be added—in this way the cylindrical part of the tube is separated from the reservoir and the air. Moreover, the test is made at a temperature of 30 to 33° C., because this degree of heat affords the best conditions for fermentation. The necessity of a defined temperature and the addition of mercury are two conditions which, though they may be easily carried out in a laboratory, cause, nevertheless, some difficulties to a practical physician. Accordingly I considered the following two questions: 1. Is the defined temperature (30 to 33° C.), which is the most applicable for the fermentation process, absolutely necessary, *i.e.*, would not the ordinary temperature of the room give us a result sufficiently accurate? 2. Is a separation of the urine from the air absolutely necessary, and if so, can we not separate them by something more convenient than mercury?

In order to ascertain whether the ordinary temperature of the room would be suitable for the test, I made the following two experiments:

Fermentation test at the ordinary temperature of the room.—1. April 23, 1886: A, urine, acid, 1.034, sugar; B, urine, acid, 1.020, sugar; C, urine, acid, 1.022, no sugar. After two hours: A, the cylindrical part of the tube empty; B, nine-tenths of the cylinder empty; C, a very small bubble at the summit of the tube. April 24, 1886: A, no fluid in the cylinder; B, fluid to the depth of about two lines in the cylinder; C, three small bubbles on the top of the tube.

2. May 8, 1886: A, urine, acid, 1.022, sugar; B, urine, acid, 1.024, sugar; C, urine, acid, 1.034, sugar; D, urine, acid, 1.010, no sugar; E, urine, acid, 1.020, no sugar; F, urine, acid, 1.024, no sugar. After one hour the sugar reaction in A, B, and C, is very apparent. May 9, 1886: A, seven-eighths of the cylinder empty; B, three-eighths of the cylinder empty; C, eight-ninths of the cylinder empty; D, E, and F, a small bubble on the top of the cylinder.

Both experiments clearly show that the alcoholic fermentation takes place even at the ordinary temperature of the room, and thus demonstrates, by the large amount of gas, the sugar reaction. Further, we see here also in the urines not containing sugar a small bubble at the summit of the tube, but this bubble is smaller than that produced at 92° F.

In a word the fermentation test can be used in the ordinary temperature of the room.[1]

To determine the second question, whether a separation of the test-fluid by mercury or another substance (as oil) is absolutely necessary or not, the following experiment was made:

May 9, 1886.—A, diabetic urine, acid, 1.034, plus mercury; B, diabetic urine, acid, 1.034, plus oil; C, diabetic, urine, acid, 1.034, without mercury and without oil; D, normal urine, acid, 1.018, plus mercury; E, normal urine-acid, 1.018, plus oil; F, normal urine, acid, 1.018, without mercury and without oil. After one hour: A, B, and C, plain sugar reaction. May 10, 1886.—A, B, and C,

[1] Virch. Arch., Bd. 102, p. 268–270.

[2] Salkowski and Leube: Die Lehre vom Harn, p. 223.

[3] The letters A, B, C, etc., signify the fermentation-tubes filled with the different fluids to be examined.

[1] I have made the fermentation test during summer and winter in my room: the temperature varied from 65 to 85° F.

the whole cylinder empty; D, E, and F, a bubble on the top of the cylinder.

Thus it clearly appears that the addition of mercury or oil has no influence on the reaction.

The above-mentioned experiments showed that the fermentation test could be used at the ordinary temperature of the room and without any addition of mercury or oil, but still it was a question whether the minuteness of the reaction had not been lessened in a high degree by this simplification.

Starting from this point of view, I took specimens of the urine of twelve healthy people and made with them all the fermentation test; to one of these specimens I added a little of a grape-sugar solution, so that the urine contained one-tenth per cent. of sugar; then this urine was also examined by the fermentation test:

June 4, 1886.—A, urine, acid, 1.020, no sugar; B, urine, acid, 1.016, no sugar; C, urine, acid, 1.024, no sugar; D, urine, acid, 1.022, no sugar; E, urine, acid, 1.020, no sugar; F, urine, acid, 1.024, no sugar; G, urine, acid, 1.022, no sugar; H, urine, acid, 1.026, no sugar; I, urine, acid, 1.026, no sugar; K, urine, acid, 1.026, no sugar; L, urine, acid, 1.025, no sugar; M, urine, acid, 1.018, no sugar; N = urine I, 10 cc. mingled with 0.2 cc. of a five per cent. grape-sugar solution, therefore the urine N had one-tenth per cent. of sugar (here the sugar could not be detected by Fehling's test). June 5, 1886.—A, B, C, D, E, H, I, L, and M, a small bubble (o o); F, = o; G and K, = o; N, = one-tenth cc., empty.

Thus we see by this experiment that the amount of gas at N (*i.e.*, in urine containing one-tenth per cent. of sugar) was much larger than in the other twelve normal specimens, and that it was in this way possible to recognize with accuracy the presence of sugar.

I intentionally took this large number of specimens of normal urine, because the size of the gas-bubble in normal urine varies in a certain degree,[1] and I thus learned that the quantity of gas produced in the cylinder by urine containing one-tenth per cent. of sugar is much larger than the largest gas-bubble in urine not containing sugar. Therefore it is evident that the delicacy of the fermentation test is not much lessened by the simplification; for even in a temperature of 92° F., and with mercury we are able to discover the presence of only one-tenth per cent. of sugar in a urine that has not been boiled.

As to the time elapsing before the beginning of fermentation, I could recognize the arising of the first gas-bubbles after fifteen to twenty-five minutes. Thus urine containing not too small an amount of sugar will show the reaction even at that early time.

As regards the number of the fermentation-tubes necessary for a test, it is sufficient to take two (instead of the three above mentioned): one (A) with normal urine, the other (B) with the suspected urine. Whether the yeast is good or not we can see by the developed bubble in A; for if the yeast be bad no bubble will be in A; and should the yeast contain sugar, then we should see in A a large displacement by gas.

All experiments I shall quote hereafter have been made in the ordinary temperature of the room and without the addition of mercury. I mention here this fact in order to avoid repetitions.

I shall now take up the second part of my theme, namely, how to ascertain the quantity of sugar by my fermentation test.

Two methods of ascertaining the quantity of sugar by fermentation have been used. One, called "chemical," consists in weighing a definite quantity of urine before and after fermentation; the difference of weight caused by the escaped carbonic acid gas gives the quantity of the changed sugar. The other, called "clinical," suggested by Roberts, consists in the difference of the specific gravity of the urine before and after the fermentation process.

In the following I shall try to make use of the carbonic acid gas space developed in the cylinder of the fermentation-tube to ascertain the proximate quantity of sugar in the urine, a method which has hitherto been used to detect merely the presence of sugar. Supposing I succeed in this point, then the fermentation test, as I make it, would gain much in value; for it would not only show the presence or absence of sugar in the urine, but it would also give an idea of the quantity of sugar present.

If the fermentation-tube were constructed in such a way that the whole quantity of carbonic acid gas, developed by the alcoholic fermentation of the urine containing sugar, would gather in the cylinder, then it would be easy to conclude from the development of the gas volume at a given temperature and degree of barometric pressure the exact quantity of sugar. But this is not the case, for as soon as some carbonic acid begins to gather on the top of the cylinder, a correspondiug quantity of fluid is pressed from the cylinder into the reservoir. The carbonic acid developed in the reservoir escapes from the surface of the fluid into the air. Thus the gas volume of the cylinder does not represent the whole quantity of gas generated, for it lacks the carbonic acid which is developed in the fluid driven into the reservoir. Although the gas volume of the fermentation-tube does not correspond to the whole quantity of evolved carbonic acid, it is nevertheless always larger or smaller, according to the greater or smaller quantity of sugar in the fluid.

It is probable that a fluid containing a certain quantity of sugar would evolve in the fermentation-tubes—as they are all of the same size—equal volumes of carbonic acid gas. If this be the case, then we could determine by experiment the gas volumes of fluids containing certain percentages of sugar, and from this would be able to conclude, from a certain developed gas volume in the cylinder, the quantity of sugar.

In order to be able to state easily the quantity of the gas volume in the tubes, I graduated the cylindrical part (containing six cubic centimetres) in cubic centimetres and fifths of a cubic centimetre. In this way the quantity of the gas volume can be read from the cylinder. The idea that one and the same sugar solution must reproduce in the tubes equal gas volumes has been verified by experiments. I found only small variations of two-fifths to three-fifths of a cubic centimetre, and they depend probably upon the differences in temperature and barometric pressure. In order to make the test not too complicated, I intentionally did not take the temperature nor the barometric pressure into consideration.

The following tables show the quantity of developed gas volumes in specimens of urine containing definite percentages of sugar. To determine these quantities several samples of normal urine were mixed with grape-sugar solutions, and the following experiments were then made:

1. May 29, 1886: A, normal urine, acid, 1.021; B, normal urine, acid, plus one-half per cent. of sugar; C, normal urine, acid, plus one-fourth per cent. of sugar; D, normal urine, acid, plus one-fourth per cent. of sugar. May 30th, 1886: A, a small bubble on the top of the cylinder; B, = $2\frac{2}{5}$ cc. gas; C, = $\frac{2}{5}$ cc. gas; D, = $\frac{3}{5}$ cc. gas.

2. May 31, 1886: A, normal urine, acid, 1.020; B, normal urine, acid, plus one per cent. of sugar; C, normal urine, acid, plus one-half per cent. of sugar; D, normal urine, acid, plus one-half per cent. of sugar; E, normal urine, acid, plus one-fourth per cent. of sugar. June 1, 1886: A, a small bubble on the top of the cylinder; B, = $5\frac{2}{5}$ cc. gas; C, = $2\frac{2}{5}$ cc. gas; D, = 2 cc. gas; E, = $\frac{2}{5}$ cc. gas; F, = $\frac{4}{5}$ cc. gas.

3. June 1, 1886: A, normal urine, acid, 1.022; B, normal urine, acid, plus one per cent. of sugar; C, normal urine, acid, plus three-fourths per cent. of sugar;

[1] These variations usually depend upon the degree of concentration of the urine by salts, as the bubble becomes larger in more concentrated urine.

D, normal urine, acid, plus one-half per cent. of sugar. June 2, 1886: A, a small bubble on the top of the cylinder; B, = 5⅘ cc. gas; C, = 3⅘ cc. gas; D, 2⅘ cc. gas.

4. June 2, 1886: A, normal urine, acid, 1.006; B, normal urine, acid, plus one per cent. of sugar; C, normal urine, acid, plus one-half per cent. of sugar; D, normal urine, acid, plus one-fourth per cent. of sugar. June 3, 1886: A, a small bubble on the top of the cylinder; B, =5⅘ cc. gas; C, = 2⅘ cc. gas; D, = ⅘ cc. gas.

5. June 24, 1886: A, normal urine, acid, 1.024; B, normal urine, acid, plus one per cent. of sugar; C, normal urine, acid, plus three-fourths per cent. of sugar; D, normal urine, acid, plus one-half per cent. of sugar; E, normal urine, acid, plus one-fourth per cent. of sugar; F, normal urine, acid, plus one-eighth per cent. of sugar. June 25, 1886: A, a small bubble = 0; B, = 5 cc. gas; C, = 4 cc. gas; D, = 2½ cc. gas; E, = ⅖ cc. gas; F, = 1/10 cc. gas.

6. October 21, 1886: A, normal urine, acid, 1.018; B, normal urine, acid, plus one-half per cent. of sugar; C, normal urine, acid, plus three-fourths per cent. of sugar. October 22, 1886: A, a small bubble on the top; B, = 2½ cc. gas; C, = 3⅗ cc. gas.

7. October 23, 1886: A, normal urine, acid, 1.020; B, normal urine, acid, plus one-half per cent. of sugar; C, normal urine, acid, plus three-fourths per cent. of sugar; D, normal urine, acid, plus one per cent. of sugar. October 24, 1886: A, a small bubble on the top of the cylinder; B, = 2½ cc. gas; C, = 3⅗ cc. gas; D, = 4⅖ cc. gas.

8. October 26, 1886: A, normal urine, acid, 1.020; B, normal urine, acid, plus one-fourth per cent. of sugar; C, normal urine, acid, plus one-half per cent. of sugar; D, normal urine, acid, plus three-fourths per cent. of sugar. October 27, 1886: A, a small bubble on the top; B, = 3/10 cc. gas; C, = 1 9/10 cc. gas; D, = 3⅘ cc. gas.

9. November 1, 1886: A, normal urine, acid, 1.022; B, normal urine, acid, plus one-fourth per cent. of sugar; C, normal urine, acid, plus one-half per cent. of sugar; D, normal urine, acid, plus three-fourths per cent. of sugar; E, normal urine, acid, plus three-fourths per cent. of sugar; F, normal urine, acid, plus one per cent. of sugar. November 2, 1886: A, a bubble on the top = 0; B, = ½ cc. gas; C, = 1⅗ cc. gas; D, = 3⅘ cc. gas; E, = 3⅗ cc. gas; F, = 5 cc. gas.

10. November 2, 1886: A, normal urine, acid, 1.018; B, normal urine, acid, plus one-fourth per cent. of sugar; C, normal urine, acid, plus one-half per cent. of sugar; D, normal urine, acid, plus one-half per cent. of sugar; E, normal urine, acid, plus three-fourths per cent. of sugar; F, normal urine, acid, plus one per cent. of sugar. November 3, 1886: A, a small bubble on the top; B, = ½ cc. gas; C, = 2½ cc. gas; D, = 2 cc. gas; E, = 3⅗ cc. gas; F, = 4⅗ cc. gas.

If we take the numbers found in every experiment, then we have:

For one per cent. of sugar the gas volume equals 5⅖, 5⅘, 5⅗, 5, 4⅘, 5, 4⅗ cc.

For three-fourths per cent. of sugar the gas volume equals 3⅖, 4, 3⅗, 3⅘, 3⅖, 3⅗, 3⅗, 3⅗ cc.

For one-half per cent. of sugar the gas volume equals 2⅖, 2⅘, 2, 2⅘, 2½, 2⅕, 2⅕, 1 9/10, 1⅗, 2⅕, 2 cc.

For one-fourth per cent. of sugar the gas volume equals ⅖, ⅗, ⅖, ⅘, ⅖, ⅖, 3/10, ⅕, ⅕ cc.

For one-eighth per cent. of sugar the gas volume equals 1/10 cc.

By this table it becomes evident that the numbers for the quantity of the gas volume in different samples of urine containing the same percentages of sugar are always approximately equal, and differ at the most by three-fifths cubic centimetres.

The average numbers quoted in the table are: One per cent. of sugar equals 5 cc. gas; three-fourths per cent. of sugar equals 3⅘ cc. gas; one-half per cent. of sugar equals 2 cc. gas; one-fourth per cent. of sugar equals ⅘ cc. gas; one-eighth per cent. of sugar equals 1/10 cc. gas.

I intentionally avoided ascertaining the quantity of the gas volumes in smaller proportions than in quarters (one, three-fourths, one-half, one fourth), in order that the differences of the gas volumes might be as great as possible, and that they could be easily distinguished from each other.

With one per cent. of sugar the gas volume is 5 cc.; thus the gas fills nearly the whole cylindrical part of the fermentation-tube. If the urine contain a little more than one per cent. of sugar, then the whole cylinder will be occupied by gas; the urine, pressed into the reservoir, will deliver all its carbonic acid into the air, and will give us in this way no means of ascertaining how much more than one per cent. of sugar it has contained. Therefore, if a sample of urine is given to us for examination, and we make the fermentation test in the *graduated* fermentation-tube, we shall be able to say on the following day, *i.e.*, after the fermentation has taken place, whether the urine contains sugar or not, and if sugar, then how much of it, whether one-eighth, one-fourth, one-half, three-fourths, one per cent., or more than one per cent.; but we shall not be able to say by the first test alone how much more than one per cent. of sugar the urine may contain.

In order to ascertain by this fermentation test approximately the quantity of sugar in urine containing more than one per cent. of sugar, it is necessary to dilute it with water.

Diabetic urine of a straw color, and with a specific gravity of 1.018 to 1.022 was usually diluted by me two times; of 1.022 to 1.028, five times; 1.028 to 1.038, ten times. The test is to be made with the diluted urine. After the reaction has been completed the gas volume of the fermentation-tube is read, and thus the quantity of sugar ascertained; in this way the original (not diluted) urine will contain, in proportion to the amount of dilution, two, five, or ten times more sugar than the diluted one.

As an example for the quantitative fermentation test the following experiment may be mentioned:

June 28, 1886: A, diabetic urine, 1.040, diluted ten times; B, diabetic urine, 1.038, diluted ten times; C, diabetic urine, 1.020, diluted two times; D, normal urine, 1.010. June 29, 1886: A, = 3½ cc.; B, = 2½ cc.; C, = 5 cc. gas; D, a small bubble on the top of the cylinder. Thus A has 3½ cc. gas = ¾ per cent. of sugar, the urine has been diluted ten times, therefore the original urine contains 7½ per cent. of sugar: B, = 2½ cc. = ½ per cent. × 10 = 5 per cent. of sugar; C, = 5 cc. = 1 per cent. × 2 = 2 per cent. of sugar; D, no sugar.

This method of ascertaining the quantity of sugar by fermentation I applied during several months in the examination of the urine of the diabetic patients of the German Hospital, and I was fully satisfied with the result. I also compared several times the results found by fermentation with the numbers given by the quantitative Fehling's solution test. As bearing on this point the following two experiments may be mentioned:

1. *Fermentation test.*—June 10, 1886: A, diabetic urine, 1.040, diluted ten times; B, diabetic urine, 1.026, diluted five times; C, diabetic urine, 1.020, diluted five times; D, normal urine. June 11, 1886: A, = 4½ cc. gas = over ¾ per cent. × 10 = more than 7½ per cent. of sugar; B, = 2 cc. gas = ½ per cent. × 5 = 2½ per cent. of sugar; C, = 1 cc. gas = over ¼ per cent. × 5 = more than 1¼ per cent. of sugar; D, no sugar.

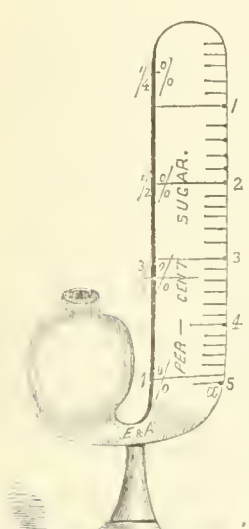
Fehling's test.—A, = 7½ per cent.; B, = 2 per cent.; C, = 2 per cent. of sugar; D, no sugar.

2. *Fermentation test.*—June 14, 1886: A, diabetic urine, 1.032, diluted ten times; B, diabetic urine, 1.038, diluted ten times; C, diabetic urine, 1.024, diluted five times; D, normal urine. June 15, 1886: A, = 2⅖ cc. gas = ½ per cent. × 10 = 5 per cent. of sugar; B, = 3⅗

cc. gas = $\frac{3}{4}$ per cent. × 10 = $7\frac{1}{2}$ per cent. of sugar; C, = $\frac{3}{5}$ cc. gas = $\frac{1}{4}$ per cent. × 5 = $1\frac{1}{4}$ per cent. of sugar; D, no sugar.

Fehling's test.—A, = 5 per cent.; B, = $6\frac{1}{2}$ per cent.; C, = $1\frac{3}{4}$ per cent. of sugar; D, no sugar.

If we now compare the results of the quantitative test by Fehling's solution with the results found by the fermentation test, we find that they are not always absolutely equal, although the difference is but slight. In this way it appears that the method of ascertaining the quantity of sugar by the gas volume in the fermentation tube gives true and approximately correct results.



The advantages of this mode of ascertaining the quantity of sugar consist in its being neither troublesome nor complicated, and it can also be employed by every physician. Urine containing albumen can be *directly* examined for sugar by the fermentation test;[1] it is not necessary to separate the albumen before applying the test, as in other methods. That is another point in favor of the fermentation test.

In order to make the quantitative determination of sugar yet easier, we have written on the cylinder figures showing the percentages of sugar. A fermentation-tube bearing this scale shows directly, by the level of the urine, the per cent. of sugar, and can be therefore called "Fermentation Saccharometer."[2]

From a study of the experiments detailed in this article we may formulate the following conclusions:

First.—The fermentation test can be made in the ordinary temperature of the room.

Second.—The addition of mercury is not necessary.

Third.—The volume of developed gas in the cylinder gives us an idea of the approximate quantity of the sugar present in the urine.

304 West Fifty-fifth Street.

Death of Dr. Margary.—On November 28th Dr. Fedele Margary died in Turin, after a long and painful illness, which he bore with unusual patience and courage, at the age of forty-nine years. He was one of the editors of the *Archivio di Ortopedia*, and was among the best known and most skilful of the orthopedic surgeons of Italy. He was one of the first Italian surgeons to practise osteotomy, and was a most ardent advocate of that method for the correction of deformities of the extremities. The last number of the journal above mentioned contained a most valuable statistical article by Dr. Margary on "Osteotomy, Osteoclasis, and Redressement Forcé." His loss will be felt, not only by his fellow-countrymen, but by general and orthopedic surgeons throughout the world.

Water and Obesity.—M. Callamand, in a critical review upon the rôle of water in nutrition, in the *Archives Générales de Médecine*, comes to the conclusion that water causes neither an increase of fat nor emaciation, and that it neither hastens nor retards nutritive changes. And he says that, in the treatment of obesity, all rules concerning the quantity of fluids to be taken are useless.

[1] I made the fermentation test several times in diabetic albuminuria, having reparated the albumen first by boiling and filtering, and also without any prepasation. In both cases the fermentation took place. The gas volumes were equal.

[2] Messrs. Eimer & Amend, 205–211 Third Avenue, New York, are the makers of this instrument, and the apparatus can be had there in correct form for seventy-five cents apiece. For the convenience of physicians a set, consisting of two fermentation saccharometers with a graduated test-tube, has been put up in pasteboard case, with directions, etc., for $1 50, complete.

Clinical Department.

NOTES OF SEVEN HUNDRED AND SIXTY-FIVE CASES OF LABOR.

Dr. L. N. Sharp, of Minneapolis, Minn., sends us the following interesting observations on 765 consecutive cases of childbirth occurring in his practice, as to the time of day at which labor terminated: Seventy of the women gave birth to children between the hours of midnight and 2 A.M.; 70 between 2 and 4 A.M.; 59 between 4 and 6 A.M.; 73 between 6 and 8 A.M.; 66 between 8 and 10 A.M.; 71 between 10 and 12 A.M.; 52 between noon and 2 P.M.; 47 between 2 and 4 P.M.; 63 between 4 and 6 P.M.; 61 between 6 and 8 P.M.; 71 between 8 and 10 P.M.; 61 between 10 and 12 P.M. Four hundred and nine of the cases occurred between midnight and noon, and 356 between noon and midnight.

These mothers gave birth to 778 children; 410 were males, and 368 females.

The deaths among the mothers were 9. Of these 6 died from puerperal peritonitis, 2 of convulsions, and 1 with placenta prævia. The deaths of peritonitis were not related to each other in the way of contagium. In the regular numbering of the cases they came as 39, 670, 703, 708, 726, 746.

In the cases of the deaths from puerperal convulsions, the first was in a primipara. The arm presented, and, after the delivery the convulsions continued up to the time of death, six hours later. In the second case it was the sixth child. The convulsions came on when the pains became severe, while the os was but little dilated. The placenta was attached, and had to be torn off. The convulsions continued, and the woman died two hours and fifteen minutes after the delivery of the child.

There was only one case of placenta prævia, and the mother died undelivered. She was not my patient, but I was called when her labor came on, and found her almost bloodless. The os was but little dilated, and I could only insert the end of the finger through it. The woman died in an hour after my arrival.

Among the number were 13 cases of twins. In 7 both children were males, in 5 both were females, and in 1 case a male and female. All of these children lived but three. In one case the child born first died before the other was born, and the second died before I left the house. In another case one child died the following day. Forceps were not used in any of these twin cases.

There were in all 22 still-born children. The cause of death in 9 of the cases was from the ill health of the mother; in some of these cases the child was dead before labor came on, and in some others the child had not vitality enough to survive the ordeal of birth. In one instance the cord came down and remained for six hours before the birth of the child, and the death was from pressure upon the cord. In 5 cases the head presented, but the children could not be resuscitated. In 5 cases the feet or breech presented; in 1 case an arm came down, and another was one of shoulder presentation.

In 4 cases only was turning resorted to; 1 case was an arm and another a shoulder presentation. In another the mother had convulsions, while in still another the head did not engage the superior strait in a proper manner.

The placenta was attached in 10 cases, and had to be torn loose. In all these cases the mother survived the labor, except in 1 case, when she died of puerperal convulsions.

The forceps were used in 26 cases; 2 of these died afterward of puerperal peritonitis; 24 mothers recovered.

Of the 778 children there were 747 head, 14 breech, 12 foot, 2 arm, 1 shoulder, and 2 face presentations.

There were 19 cases of post-partum hemorrhage, with 1 death. In these I have only counted those severe cases in which the mother became pulseless from loss of

blood, where the uterus did not contract, or concealed hemorrhage endangered the life.

Nine mothers had puerperal convulsions, and two of these died. In one case the convulsions preceded labor, and the mother died in an apoplectic condition. In another the eclampsia came on while labor was progressing and continued after the child was born, and the mother died suddenly two hours later. In the other cases the convulsions came on during labor, and in all, save one, continued for a few hours afterward, when the mother regained consciousness and all went well. In one case, with the last expulsive pain came a convulsion, the child was born, and no more trouble ensued.

There were two cases of phlegmasia alba dolens. One in the case of an arm presentation, where the child was turned, and the other followed excessive post-partum hemorrhage. Both cases recovered.

Inversion of the uterus occurred but once. The mother had a moderate labor with her first child. In a few minutes I made gentle traction on the cord, and the inverted uterus came out through the vulva. The placenta was firmly attached to the fundus. I peeled it off, and with my fingers against the fundus, carrying the hand in the vagina, I had the satisfaction of finding the uterus properly returned. The shock to the mother was but slight, and she recovered without an untoward symptom.

Craniotomy was performed twice. In both cases the child's head was large, and repeated efforts with forceps, in the hands of consultant as well as my own, failed to bring the child. One case was complicated with puerperal convulsions, and turning could not be accomplished. The mother died a few hours after the extraction of the child. In the other case the mother died of peritonitis, which rapidly followed the extraction of the infant.

In one case, in which both mother and child did well, no blood was lost during labor, and no lochial discharge followed.

In three cases the funis came down ahead of the child, and only one child of the three was saved. In one case the funis had been down six hours before I saw the case; the child was dead.

The cord was so short in one case that it broke during the birth of the child.

One seven-months child was born exactly nine months after a former labor. The child lived.

There was one case of hernia cerebri; the greater part of the brain-substance came through the posterior fontanelle into the sac. The child breathed for a few minutes after birth and died.

Two cases of hydrocephalus were met with. In both the head was punctured and the water let off, when the labor proceeded to termination. The mothers both made good recoveries.

Three cases presented deficient development: One a hare-lip; one in which the two parietal and the occipital bones were wanting; in the other the bones were absent from the arch, over the eyes, of the frontal bone to the commencement of the spinal cord. A part of the temporal bones and the bones at the base of the brain were present, as were also the bones of the face.

Of the 765 mothers, the fact may be mentioned that 19 were unmarried; they all made good recoveries.

In all these cases I do not know of a ruptured peritoneum or a ruptured os; yet the os might have been ruptured and escaped observation, but I never found it in any of the cases which came to me for gynecological treatment. I have never, in my obstetric cases, met with vesico-vaginal or recto-vaginal fistula. I always gave my cases all the time which appeared to me consistent with the physiological act, and only interfered when nature appeared to act tardily, or was insufficient to effect safe delivery.

In some cases I attended the same woman in as many as seven successive confinements, and found the time of day in the labor was different in every case; so also the character of the labor. Sometimes it would be speedily over in a woman who at another time would have a protracted labor. The presentation at one time would be no guidance for another subsequent presentation in the same woman. The time of rupture of the membranes was not the same in different confinements; neither, if the woman had a bad getting up at one time, could an inference be drawn that it would be the same at another time, if the health was generally good. Each individual case appeared to have its own characteristics, even in the same woman. And yet there is a sense in which each woman has her own type of delivery.

INFLUENCE OF POSITION ON THE PROGRESS OF LABOR.

Dr. S. Haynes, of Saranac, N. Y., writes: "On May 23, 1867, I was in attendance on Mrs. —— in her first labor. It was a tedious one, and had continued for many hours without making satisfactory progress. The thought occurred to me that perhaps the patient may have occupied a particular position for some time during her pregnancy; if so, that by her resuming that position now, the uterus, with the contained child, would assume its normal position. On making the inquiry I learned that for a long time she could rest or sleep only on her right side. The patient now took that position, when, happily, her labor took on a favorable turn and terminated in due time. The pronounced good results in this case following the assumption of that position which the patient had been compelled to occupy for a length of time during her pregnancy—when in the lying position—decided the writer to continue his observations on this point, in the future, and this he has now done for almost twenty years. According to this experience it has been ascertained that in many difficult or tardy labors the progress of the case is profoundly influenced by placing the woman in that position which she has been compelled to take for her own comfort during her term of pregnancy. But further, the writer has observed that in making an examination in the first stage of labor, in case the patient has been compelled to lie on the one side for a length of time before confinement, the os uteri may be reached much more readily on placing the patient in the position which she has previously occupied from choice or necessity."

TWO CASES OF POISONING FROM ANTIPYRINE AND NUX VOMICA.

Dr. R. B. Henderson, of Wilton, N. C., reports the following cases:

Case I.—A girl ten years of age was first seen on October 7th, and was found to be suffering from remittent malarial fever, having a temperature of 104° F. About three grains of antipyrine were given, and sulphate of quinine was ordered for the next day. On the 13th tincture of nux vomica was ordered to be given in three-drop doses three times a day. She was seen again two days later and was found to be doing well, although she had been restless at night. The temperature was 102° F. Thirty grains of antipyrine were ordered to be given in two doses at two hours' interval. A few hours later the uncle of the patient called and asked what had been left for the child to take. He was told what the drug was, and said: "Well, sir, it killed her in fifteen minutes." Dr. Henderson went with him and found his patient really dead. He was informed that the medicine had caused an intense burning in the throat and stomach, and that the patient had vomited a watery fluid, then fainted, and was dead. There were no convulsions nor anything to indicate that nux vomica had caused the death. The family said that the child had at times complained of palpitation of the heart, and they all thought she died from heart disease. This was also the conclusion of the writer, but it was modified considerably by the occurrence of a second similar case.

Case II.—A young lady living in the same neighborhood, and suffering from the same type of fever, was treated at first with quinine in doses of thirty grains a day. As this seemed to have no appreciable effect upon the temperature the writer gave her four grains of antipyrine and remained with her half an hour or more to see if any unfavorable symptoms developed; as none did he left six grains to be given in three doses at hourly intervals. No unpleasant effects followed. The next afternoon the fever was up again. Not having any antipyrine, Dr. Henderson increased the quinine ten grains for that day and left tincture of nux vomica, to be taken in five-drop doses three times a day. A few days later he called and found the temperature 104⅘° F. in spite of the fifty grains of quinine, so he concluded to try antipyrine, administered five grains (the patient had taken five drops of tincture of nux vomica an hour before) and awaited results. In five minutes she complained of a burning in her throat and stomach and then nausea, and vomited a watery fluid. After the vomiting she felt no better, but was sicker, and felt weak, and her pulse was feeble. The writer gave her ipecac and produced emesis, and then gave her whiskey and water freely, applied cold cloths to the back of her neck, gave half a teaspoonful of tincture of digitalis, and then more whiskey and water, keeping the patient in the sitting posture for a while. She asked to be laid down, and in about a minute the muscles of her neck began to stiffen, the fingers were drawn, and respiration was nearly suspended. She was immediately raised to the former position and fifteen or twenty grains of chloral hydrate were given, and the respirations being intermittent, artificial respiration was made for five or ten minutes, and then thirty minims of whiskey and ten minims of tincture of digitalis were given hypodermically. Finally ten minims of aromatic spirit of ammonia were injected, and the patient had no further bad symptoms. She was kept under the influence of chloral for the following twenty-four hours.

The patient said that she was perfectly conscious during the first part of the attack, but could not speak, and that she lost consciousness when the chloral was given, and did not know anything for several hours. Dr. Henderson concludes: "I submit this report, though imperfect, in the hope that someone will tell me what was the active principle in the two drugs to produce the condition that followed their administration so near together. Each patient had taken antipyrine without nux vomica, and nux vomica for several days without the antipyrine, and no bad effects followed. When they were taken within an hour of each other, however, death followed in one case and nearly did so in the other. I will state that I had been in the habit of treating cases of this nature with quinine in the morning and antipyrine in the evening, when the temperature was high, and had never heard any complaint from it, though I had given it in twenty cases before the first accident, and was highly pleased with the results. Since the last case reported I have not used it. I would like very much to use it, but shall wait until I can get some information as to its physiological action."

FOREIGN BODY IN THE INTESTINE.

Dr. Clarence King, of Machias, N. Y., writes: "I have noticed several letters in The Record relating cases of foreign bodies being swallowed by children. While attending my last course of lectures I boarded in a family where there was a little girl about nine or ten months old, who swallowed its mother's breast-pin. The pin was of gold, an inch and a half or two inches in length, and had several sharp edges and corners on it. Besides this the clasp was uncaught, thus increasing the liability of the pin to become lodged in the intestine. The child obtained the pin from its mother's clothes unknown to her, and it was only when the pin was missed that the suspicion arose as to what had become of it. The child suffered no inconvenience, except a coughing and crying fit at the time it was supposed that she swallowed it. Her father, who was a physician, gave her a full dose of castor-oil, yet it was not until two days afterward that the pin was passed per rectum. Besides this case several others have come to my knowledge in which coins, buttons, and other playthings have been swallowed, and I have never yet heard of any ill effects following. I have therefore concluded that this is not a very rare accident or one of great clinical importance. This last statement I would modify according to the article swallowed. Expectancy, or the administration of a light cathartic, seems to be all the treatment necessary."

Progress of Medical Science.

Overfilling and Dilatation of the Colon.—At a recent meeting of the Chicago Medical Society Dr. J. S. Jewell read a paper on this subject. He said that for the last ten years this subject had attracted more or less attention. During the last eight or ten years he had accumulated a list of over five hundred carefully studied cases, in which the condition named existed, and concerning which he gave his observations. His mode of investigating the cases in which the overfilling existed has been as follows: The patient is stripped so that the abdomen is bare, the abdominal walls being relaxed. Then he takes a plate of soft rubber, at least two inches in length by an inch and a half in breadth, and one-fourth of an inch in thickness, and a heavy steel hammer, quite as heavy as the ordinary surgical bone-hammer. With this the abdomen is carefully percussed over the track of the colon from its origin, tracing it up under the liver, across and down to the sigmoid flexure. Thus percussing over the track of the colon and carefully locating every mass of fæces (even in persons with fleshy abdominal walls), he has been able to get at its course and contents. Out of these five hundred cases, perhaps one hundred have said that they were as "regular as clockwork" in having movements from the bowels. But upon examination, in most such cases the colon was found to have variable quantities of fæcal material lying in it. The part of the colon most subject to dilatation is the sigmoid flexure and the descending colon. At the flexure of the colon, deep in the left hypochondriac region, almost as frequent as in any other part of the course of the colon, he had found it dilated and filled with fæcal matter. The next most common situation is the transverse colon; last of all the cæcum. The common way is to find masses of fæces lying in lumps here and there, not filling the entire intestine. In most cases investigated, the colon was dilated, apparently, in some part or other, all the way from two to three times its proper calibre. This class of patients are all liable to become "bilious," and are habitually taking cathartic pills, mineral waters, etc. In every or nearly all instances, Dr. Jewell could trace their "biliousness" to gradual filling up of the colon, and the disturbance produced from this cause in the digestive apparatus higher up. The change in the secretions of the mouth, the bad breath, the unhealthy odor of the skin produced by absorption of fetid substances from the rotting masses in the intestine, together with the coloring matter in the same, gives the skin of the patient a peculiar dirty, sallow color. One of the first things to occur in addition to the dilatation and weakening of the muscular coat of the colon by accumulation of material in it is irritation of portions of the mucous membranes where the fæcal masses lie, producing local catarrhs. This occurs with a frequency and to an extent that no one would suspect, unless they set the patient or nurse to carefully watching the stools. The next important factor in these cases is irritation of

the peripheral ends of the sensory nerves of the intestinal mucous membrane, irritated by contact with the fæcal masses. The nerves that return from the colon probably enter the spinal cord, at a level not lower than that of the tenth or eleventh dorsal vertebræ. Above the level named they probably enter the cord at various points higher up in the lower two-thirds of the dorsal cord, not to mention direct medulla connections, etc. Along these nerves are propagated the irritative impressions from the colon into the spinal cord or medulla, and thereby "switch" connections, outgoing or reflex impulses, are sent to other portions of the body, producing thus various forms of disorder to be referred to later. He believes that he has not found one case in twenty of ordinary melancholia that has not had its origin partly, or in some cases apparently entirely, in overfilling of the colon. Headache, and a great many transient disorders referred to the head, more frequently owe their origin to this source than he had ever supposed. Next is the influence upon the circulation in general, especially upon the heart's action, lowering its tension, and thus giving a feeble pulse. Dilatation of the colon often causes a sluggish capillary circulation, and this accounts for the frequency with which patients complain of cold extremities. Dr. Jewell has found patients who could not remember having had naturally warm feet for years, when upon removal of the masses in the colon the feet would become warm. In insomnia he has found the condition of the colon described to be a frequent cause, the colon being the seat of the original disorder. There is lowering of the vascular tension nearly always in these cases; hence the feeble nutrition and feeble circulation in the brain, not to mention other parts. The next most important result of dilatation and overfilling of the colon is the fact that these masses of retained fæcal substance in various ways poison the individual, by absorption of septic material. He has had three cases of epilepsy that he traced exclusively, as far as could be told by the results of treatment afterward, to disease in the left extremity of the colon caused by fæcal accumulations, and when the disorder was removed by proper means he was able to relieve the epilepsy. For the removal of these masses, as a rule, he does not use purgatives, but injections are given after the following plan: A large bag fountain-syringe, holding half a gallon, is adjusted at a convenient height from the floor, the patient lying down in the knee-chest position. The fluid should flow with considerable force until it makes its way past the upper sphincter, which is at a lower part of the sigmoid flexure; pass one quart to one-half gallon of water, according to the size of the colon, so as to fill the entire organ to the cæcum. In some instances he has been able to introduce as much as a gallon of water into the colon, the patient feeling no serious inconvenience from it, and a half-gallon is a common amount to introduce. The patient is then directed to lie down on the left side, and by a proper massage over the ascending colon the liquid is moved with the contents of the bowel toward the rectum. This should be done once or twice in the twenty-four hours until the colon is clear, and by this means it should be kept so. After this has been accomplished give the patient something that will act as a stimulant to the nervo-muscular coat of the colon. A good prescription for this purpose, he has found, should contain in pill or capsule form extract of cascara, a little belladonna, strychnia, hydrastis canadensis, and aloes. By care the colon can be kept clear, and the disorders of the stomach usually disappear, the secretions of the mouth are improved, the skin assumes a healthier color and loses the distinctly fæcal odor that it frequently has.—*The Medical Age*, October 11, 1886.

Spontaneous Shedding of Nails in Hysteria.—Dr. T. Falcone, of Naples, records a case of hysteria, prolonged and aggravated, in the course of which there was spontaneous shedding of the finger- and toe-nails. The patient was fifty years of age, and since 1870 had, after a mental shock, been subject to hemicrania and other nerve symptoms, including paraplegia, hyperæsthesia, globus, etc. She recovered, but after remaining well for six years, the symptoms returned on the occasion of her first visit to the grave of her son, whose death had in the first instance been the exciting cause of her attacks. The affection of the nails was preceded by tingling in the fingers and toes, especially the thumbs and great toes, followed by suppuration in the bed of the nail. It was noted that on the right thumb the new nail was formed directly from the bed of the nail by proliferation of epithelium, which assumed a horny character; but on all the other affected fingers and toes the repair took place in the usual way, viz., by growth from the matrix. The condition altogether was regarded as a dystrophic one, due to disordered nerve function.—*The Lancet*, October 30, 1886.

The Internal Treatment of Gonorrhœa.—At a late meeting of the Berlin Medical Society, Dr. Posner stated that, although what had been learned about the gonococcus was extremely interesting, it had not given us much that was practical so far as treatment was concerned. Local anti-bacterian treatment had not yet been followed by brilliant results, and to-day we treat gonorrhœa with the old remedies, and combat it especially with the various forms of injections. These injections are not valuable in that they destroy the gonococci, but because they cure the inflammation of the mucous membrane. Internal medicines act beneficially by passing off in the urine and cleaning out the urethra. Dr. Posner speaks highly of sandal-wood oil, which has such a reputation in France. He has used it much because he has become convinced that injections, although they work very well in some stages of gonorrhœa, still are not well borne by many patients and may, indeed, act injuriously. From the speaker's observations he believes that many gonorrhœas which would get well of themselves under suitable régime are often kept up artificially by injections. He had used the sandal-wood oil in fresh cases, and could state from his own observations that, under all circumstances, it was better borne than the other balsams, and that it exerted a better influence on the disease. In those complications of gonorrhœa in which we have to cease injections on account of epididymitis, cystitis, prostatitis, etc., this drug is greatly to be recommended. Dr. Posner had repeatedly seen cases of acute catarrh of the bladder, with bloody or turbid urine, improve and the urine become clear after a few doses of the sandal-wood oil. In old cases of cystitis and prostatitis it was also beneficial and always acted favorably on the tenesmus, and cleared up the urine. In chronic gonorrhœa, less stress was laid upon its beneficial action. The purity of the preparation was of great importance. The most elegant form to use was the French preparation which went under the name of "santal midi," put up in capsules which were easily taken and well borne. The patient took daily from ten to twelve of the capsules of five drops each. If the oil did not agree with the patient, a little hydrochloric acid might be added to the doses, and, to improve its taste, a few drops of oil of peppermint. Altogether, according to the speaker's idea, sandal-wood oil was the most efficacious internal remedy at our disposal.—*Deutsche Medizinal Zeitung.*

Cataleptic Sleep.—A case is related in *El Siglo Médico* of a recruit sent to Havana from the North of Spain. After having been in Cuba some months he began to suffer from homesickness and finally fell into a cataleptic sleep in which he remained for fourteen months, neither speaking nor moving. He was fed every six or eight hours with milk. He was at last aroused by hearing the music of a dance peculiar to his native place, and made a perfect recovery.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 22, 1887.

THE PRESENT CONDITION OF THE MEDICAL PROBLEM.

THE numerous comments made on our recently published prospectus of the "Little-toe Dispensary" show that its satire was appreciated. Its statements served as apt illustrations of the existing state of affairs. Despite all that has been said concerning the abuse of medical charities, the work of making medical paupers goes steadily on, and even seems to be putting forth some new agencies of evil. An occasional warning voice is raised, but seemingly without avail. In these first few weeks of the present year of grace it is well for us to take an inventory and see how the public and the profession stand on this question. Party platforms are revised by political managers to suit the needs of varying campaigns. Are our old arguments still valid and forceful, or do they need revision?

If anyone wishes to reform an abuse, he must know no such word as discouragement. He must rely for his inspiration on the truth of his cause. The honesty of his motives will be impugned. He will be accused of posing for the sake of notoriety. The subject of axe-grinding becomes a prominent topic in the conversation of his critics. But the work of reform goes steadily on, and, if truth is evolved, the battle is finally won.

For the past two or three years THE RECORD has freely criticised the improper management of some of the medical charities of New York. It has not hesitated to speak plainly. The basis of all facts and figures published has been the annual reports of the institutions in question. No statement has been made which these authorities would not verify. A free discussion has followed concerning the evils complained of, and the remedies needed. Our columns have contained all shades of opinion from the various parties to the controversy. One public meeting has been held. A committee was appointed, consisting of representatives of the various institutions, to see what could be done. This committee has not, to our knowledge, made any public report.

The whole question may be summed up in these few words. With only two or three exceptions, no pains are taken to select the worthy and reject the unworthy applicants for medical charity. Ask any physician in New York, and he will admit the existence of this evil. We are not combating a shadow.

And yet, in the face of all this, we find the dollar-a-month system still in vogue at one institution, and the managers of another erecting a dispensary in the middle of a section of wealthy residents, and in a district already fully equipped to care for all the sick poor within its borders. Almost a public protest has gone up against this insult (for such it is) to those agencies in our midst which are trying to reduce our cumbrous system of medical charity to a state of simplicity and greater efficiency.

On the other hand, we note with pleasure the steadfastness of those institutions where the seed of reform has been planted. Already it has sprung up and borne some fruit. The profession has become aroused, and this is the first great result. It lies in its power to bring the institutions that so grossly err to terms. In spite of one or two discouraging features, we regard the outlook as on the whole hopeful.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

WE have received the "preliminary announcement of readers and papers," and it foreshadows one of the most successful meetings in the history of the Society. The list of those who have promised to contribute to the proceedings is made up of the names of representative men in the medical profession of this State, and their scientific contributions cannot be outranked in any medical society in this country.

Inasmuch as the announcement does not appear like a programme, with the order in which the papers will be read, we assume that this arrangement will constitute a part of the labor of the Business Committee. On that assumption we offer a suggestion, which we believe will promote the best interests of the Society, and it is that the contributions of the delegates and the permanent members should receive the preference in the order of the exercises. We have been led to make this remark by the fact that, at the last annual meeting, there was an undercurrent, mild, perhaps, of disapproval of the order which permitted the reading of a contribution in the first morning session, by a gentleman who had not even been made an invited guest. The paper was an excellent contribution, but the regulations and precedents were so warped by the order that it did not look well, to say the least. The experienced Business Committee of this year should be able to arrange this matter so that the rights of the delegates and the permanent members will be adequately protected.

SO-CALLED PURE VEGETABLE REMEDIES.

THERE is a curious superstition in the lay mind that all vegetable remedies are comparatively harmless, while mineral substances are much more injurious to the human economy. This superstition or prejudice in favor of the vegetable kingdom is always skilfully appealed to by the quack, whether he be only an "Indian doctor" or represent the supreme development of charlatanism in the person of a "professor" who gives free lectures to the public on nervous debility, suborning the daily press for his purposes. The prejudice, perhaps, originated some fifty years ago, when the public and the profession began to realize that there was too much giving of antimony and mercury. It always received moral support from the old women who only knew how to brew

herbs and feared what they did not understand. Besides, vegetable medication belongs to the childhood of the human race. The use of mineral drugs is the result of the acquirement of scientific knowledge and the general advance of civilization. It is no wonder, therefore, that it has been regarded with suspicion by the ignorant. But the fact is the prejudice is entirely without foundation. At the present time a list of the poisons used as drugs will show a great preponderance of the vegetable kingdom. We have, for example, such universally consumed substances as alcohol, tea, coffee, and tobacco. These "purely vegetable substances" alone do a hundredfold more to poison and deteriorate the human system than does the whole mineral pharmacopœia. But besides these we have opium, Indian hemp, and the whole seductive list of "purely vegetable" narcotics. By far the most powerful poisons to the system are of purely vegetable origin. Such, for example, is curarin, which produces its effects in doses of $\frac{1}{100000}$ of a grain; and strophanthin, of which a solution containing one part to ten million of water will kill the exposed heart of the frog. The most subtle and evasive of poisons is the active principle of the "purely vegetable" digitalis purpurea, while strychnia has probably poisoned more animals and human beings than any drug but arsenic.

Take it as a rule, therefore, the most violent poisons and the substances that produce the most deleterious effects on the human system are from the vegetable kingdom. The mineral drugs which may cause harm are few in number, and, if we except arsenic, are not especially violent poisons. There is a considerable amount of poisoning from lead, but not through its medicinal use, and the same may be said at the present time of mercury.

In fine, it is the purely vegetable drugs which are the most dangerous, because it is these which stimulate the brain or benumb the senses, induce morbid habits, and eventually establish physical degeneration.

We wish that the public could be made to understand this when it is confronted with alluring notices of the perfect safety and harmlessness of "purely vegetable" drugs.

CONTRIBUTIONS TO LONDON HOSPITALS.

New York considers itself a rich city and generous in its gifts to charitable objects, but it must be confessed that we are poor and provincial compared with what private citizens of England—chiefly London—have done for medical charities. In the past year about twenty-five persons have given donations or left legacies, mostly to London hospitals, to the amount of over two million dollars. One lady alone leaves, in default of her daughter having issue, $450,000 to twenty-odd medical charities in London. A gentleman named Walpole leaves $925,000 to be distributed among a dozen hospitals. A number of others leave sums ranging from $15,000 to $60,000. Yet the London medical press is constantly complaining of the poverty of the hospitals, and extraordinary efforts have of late been made to increase the regular annual contributions, in which the two millions referred to is not included. Is it not quite possible that this hospital work is being overdone? It has a pauperizing effect to eventually persuade well-to-do people to get their medical services free of charge.

THE TREATMENT OF PHTHISIS BY LARGE DOSES OF TANNIN.

The French are most prolific in devising new methods of treating phthisis. No sooner is the medicated gaseous enemata process well established in the hospitals than Drs. Arthaud and Raymond announce something still better, or at least simpler. They began by experimenting on rabbits, in order to find some substance which would render them non-susceptible to inoculations of tuberculous matter. They found tannin to produce some very remarkable results. The Paris correspondent of the *British Medical Journal* writes: "Six rabbits were treated for a month with doses of tannin, varying from fifty centigrammes to one gramme; after two successive inoculations, one with lung-tissue from a patient who had died of acute tuberculosis, the other with miliary tubercle from a hospital patient—no trace of infection was observed, while three other rabbits, to which tannin had not been given, succumbed in consequence of inoculations with the same material. These experiments suggested a mode of treatment which has been adopted with excellent results in over fifty cases. Tannin was given in doses of from two to four grammes a day, and the improvement was visible at the end of a fortnight, the patients had increased in weight, and no relapse occurred. In cases of acute tuberculosis, both in children and adults, it sometimes happens that the symptoms appear less favorable; but, at the end of a week or a fortnight, the patient's condition improves, even when fatal results have been feared. From these experiments the following conclusions may be drawn: (1) That tannin is preferable to sulphur of carbon or iodoform in the treatment of tuberculosis; (2) that animals submitted to this treatment for a month offer great resistance to the action of tubercular virus."

THE REPORT OF THE SURGEON-GENERAL OF THE UNITED STATES ARMY.

The Surgeon-General's report for the year ending June 30, 1886, is one deserving of special attention. The statistics showing the morbidity and mortality of the soldiers are, as usual, most complete, but, in addition, the Surgeon has added a number of scientific contributions from the members of the medical staff, thus giving to the volume an especial value.

The tables given show that the actual number of admissions to sick was 32,990, or 3,839 less than for the preceding year. Compared with the average rate for ten years preceding, the admissions were about one-fifth less. A greater proportion of invalids was furnished by troops under thirty-one years of age, while up to the age of twenty-five the rate proved so much above the mean for the whole army that the Surgeon-General states it may be fairly questioned whether the services rendered by these young men are equal to the cost of their maintenance. Men of Irish birth furnished the highest mortality rate, or 7.9 per 1,000; the English stood next, and the Germans third.

The two worst months of the year were August and January; the healthiest month was April; 184 surgical operations were performed during the year, 37 being consequent upon shot injuries.

The Museum received 436 new specimens during the year, and the total number is 9,583.

The Library received an addition of 10,708 books and pamphlets, making the total number 106,631. The third and last volume of the "Medical and Surgical History of the War" is now in the hands of the printer.

The scientific articles include eight contributions on various topics, and a series of fifteen reports upon aneurism, which, taken together, form an interesting contribution to the subject in question.

PASTEUR AGAIN.

The experiments of von Frich, of which we give an account elsewhere, are the most damaging arguments against Pasteur's preventive inoculations that have yet been brought forward. If, as now appears probable, the whole of Pasteur's claims are shown to be baseless, and all his inoculation work a mere conjuring with hypodermatic syringes and useless solutions, the collapse will be a tremendous one. Pasteur will have won a world-wide notoriety, secured honors, government appropriations, and thousands of dollars from private individuals, all through the glorification of a little operation which is futile, if not absolutely dangerous. Medical opinion upon Pasteur's work has uniformly been one of expectancy. From the very first it was recognized that his experiments were not demonstrative, nor his conclusions unassailable. The public, however, will be inclined to resent the whole affair as an imposition, if not downright quackery. This view will be natural, but at the same time unjust, for Professor Pasteur is beyond doubt sincere in his beliefs.

HYSTERIA AND THE TUBERCULAR DIATHESIS.

A theory has recently been put forward by Dr. Grosset (*Gazetta Medica di Torino*) to the effect that hysteria is frequently but a manifestation of the tubercular diathesis, which may or may not be accompanied by other more evident signs of this affection. A clinical demonstration of such an hypothesis is, of course, out of the question, but the author seeks to prove his theory by the facts obtained from a study of phthisical families. He says, for example, that he has observed families in which one child of tuberculous parents may die of pulmonary phthisis, another may have tubercular meningitis, while a third will perhaps give no evidences of any of the ordinary forms of the affection. But this third child, the author asserts, is only apparently free from the effects of this diathesis; he shows no tubercular trouble, but he is markedly neuropathic, and either becomes hysterical or falls a victim to mental disease. The same individual may also, in later life, acquire some form of tubercular disease. Another fact which Dr. Grosset has observed, and which he regards as confirmatory of his views, is that the children of this hysterical individual, in most cases, become phthisical or betray other evidences of the transmitted tubercular diathesis.

Tuberculosis, he says, is, like all diatheses, an essentially general and constitutional disease, and pulmonary phthisis is one, and only one, of its manifestations, just as neuroses in general, and hysteria in particular, may be another. The affection may declare itself at one time by cerebral symptoms, at another by pulmonary signs, but these various manifestations are expressions of one and the same condition, viz., tuberculosis. This alternation of symptoms between the nervous system and various organs is compared to that observed in other affections, such as typhoid fever, rheumatism, gout, etc.

The author is not very convincing in his arguments, but he may, nevertheless, be making advances in the right direction; and his efforts to solve the mystery of hysteria may give occasion to further investigations which will throw a brighter light on this now obscure subject of the etiology and pathology of hysteria.

THE MICROBE OF SMALL-POX.

Several observers during the past twenty years have reported that they found micro-organisms in the blood, tissues, and contents of the vesicles in small-pox, but their conclusions have not been entirely satisfactory, owing to faulty methods of research, as well as to the want of unanimity among them. Some of the more recent investigators, indeed, among whom are Klein, Strümpel, Cornil, and Babes, admit that their results are far from conclusive, and affirm that the specific microbe of variola has not yet been isolated.

The latest writer on this subject, however, Dr. A. Marotta, claims to have found the micro-organism which has hitherto eluded the search of other investigators. He has made a series of careful experiments by cultures and inoculations, the report of which is published in the *Revista Clinica e Terapeutica* for November and December, 1886. He found constantly in the lymph of the variolous pustules a special form of microbe which he calls the micrococcus tetragonus. These micrococci are arranged in groups of four, and present somewhat the appearance of sarcinæ. They are readily cultivated in gelatine, agar-agar, coagulated blood-serum, and egg-albumen, but not on potatoes. The colonies are of a clear orange-yellow color, and of rather considerable thickness. Their growth is slow in gelatine, requiring about a month for the complete development, but is more rapid in blood-serum. The liquefaction of the culture medium also takes place slowly, and the reaction, after this has occurred, is intensely alkaline. The medium must be alkaline in order to permit of successful culture experiments.

Inoculation experiments were made upon calves, dogs, and guinea-pigs. Inoculation with the seventh generation of cultures in calves produced pustules identical with those of vaccinia, while the results in the case of dogs and guinea-pigs were negative. Injections into the subcutaneous tissues of these animals gave rise to no suppuration, whence the author concluded that the microbe had nothing in common with pyogenic micrococci.

Dr. Marotta's experiments seem to have been conducted carefully, and with all the precautions necessary to exclude error, and it is safe to conclude that in the cases seen by him there was present in the vesicles a micrococcus tetragonus, but whether he has discovered the specific microbe of variola is another question. Time and further experiments may possibly demonstrate the correctness of his belief.

News of the Week.

The Alumni Association of the Woman's Hospital of the State of New York.—This association held a very successful annual meeting at the Academy of Medicine on Wednesday last, at which several interesting papers were read. In the evening Dr. James B. Hunter gave a reception to the members at the University Club. There was a full attendance, and a very enjoyable evening. The association is a unique one of its kind, and its success is an example worthy of imitation.

The Medical Law of Indiana.—Indiana is a progressive State, and its physicians have of late years taken an active and effective interest in promoting the welfare of the body medical. A registration law has been secured, but, like most of such laws when first enacted, it has some serious defects. One of the most glaring of these is that of the clause which allows the county clerk to issue a license to practice to any physician who files an affidavit stating that he has graduated from a reputable medical college. The clerk is thus made judge of what are the reputable medical colleges in this and other countries. Manifestly he is very unlikely to be competent to decide upon such a point. A question of this character should rest either with a board of medical examiners or with the State Board of Health. Experience has shown that a very good estimate of the real character of our numerous medical institutions is usually made by bodies of this kind. The activity of the Illinois Board of Health, and the vigilant scrutiny of educational measures now kept up by medical journals, have made the task of weeding out the quack institutions comparatively easy.

The International Medical Congress.—The *Berliner Klinische Wochenschrift*, speaking editorially of the International Medical Congress, says that though the foreign guests may not see a complete representation of American medicine, and though the absence of many well-known American physicians may make of the meeting a kind of Rump Parliament, yet there will be many interesting sights and experiences which will amply repay the visitor.

The First Cæsarean Section performed in the West, if not in this country, was done by Dr. Richmond, of Indianapolis, by candle-light. So says Dr. W. H. Wishard.

A New Bacteriological Journal.—The interest in bacteriological studies has developed most rapidly since the admirable methods of research devised by Koch have been generally adopted, and have commenced to bear fruit. Bacteriological laboratories have been established, during the past two or three years, in the various countries of Europe and in America, and the recent literature of the subject is extensive and rapidly increasing. The fact that this literature is scattered through journals published in several different languages, and that many of these journals are scarcely known to the profession in this country, has made it a matter of difficulty to keep *au courant* with the progress of knowledge in this direction. In future the matter will be greatly simplified, for those who read the German, by the publication of a weekly periodical entitled *Centralblatt für Bacteriologie und Parasitenkunde*. The publisher is Gustav Fischer, of Jena, and the journal is under the editorial management of Dr. Oscar Uhlworm, of Cassel, assisted by Professor Leuckart, of Leipzig, and Dr. Loeffler, the distinguished bacteriologist, of Berlin. The editorial staff of the journal will include a large number of "*Mitarbeiters*," located in all of the countries of the world in which bacteriological studies are pursued. Dr. G. M. Sternberg has been requested to act as "co-laborer" in America, and will forward to the editors, for review, any papers which may be sent to him in which original experimental work of value is recorded. He requests that reprints may be sent to him in duplicate (address, Johns Hopkins University, Baltimore, Md.).

The First Course of the Middleton Goldsmith Lectures, under the auspices of the New York Pathological Society, will be delivered at the College of Physicians and Surgeons, corner Twenty-third Street and Fourth Avenue, by M. Allen Starr, M.D., Ph.D., Professor of Nervous Diseases, New York Polyclinic, on "Multiple Neuritis, and its Relations to Peripheral Neuroses." First lecture will be on Tuesday, January 25, 1887, 8 P.M., on the "History of Multiple Neuritis, the Pathology of the Disease, its Varieties and Etiology; Peripheral Neuroses traceable to Neuritis." Second lecture on Friday, January 28, 1887, 8 P.M., on "The Clinical Picture of Multiple Neuritis, Diagnosis of the Disease, Prognosis, and Treatment." Members of the profession cordially invited.

Cerebral Rheumatism and the Death of the late General Logan.—A correspondent, who signs himself "A Country Practitioner," writes as follows: "Will not your recent editorial upon 'The Death of the late General Logan' be calculated, on cursory reading, to form a false impression in the minds of the profession at large regarding the common complications and mortality of rheumatism? It is almost impossible to find it recorded that organic cerebral disease is secondary to acute articular rheumatism, even though it may be—the usual way of fatal termination being by: 1, Cardiac lesions; 2, kidney diseases; 3, hyperpyrexia. Ulcerative endocarditis, pericarditis, and nephritis, all are causes of delirium, stupor, coma, death, whether from an embolus, thrombus, pyæmic or uræmic poisoning, or simple exhaustion from elevated temperature. What I am contending for is the specific complication inducing congestion of the brain as one of its symptoms. It evidently was not congestion that killed General Logan, or paralysis from compression, but the complication behind your generalizing statement is what accomplished the fatal issue, and that is what we wish to know. We will not array our authorities *pro* and *con* the usual causes of death in this disease, but ask the physician lately in attendance to favor us with an elucidation."

The Hospital Saturday and Sunday Collection has reached the sum of $48,000, with the prospect of its amounting eventually to about $52,000.

The Weekly Medical Review.—Dr. Robert Lierking retires from the editorship of this able journal, and is succeeded by Dr. Benjamin J. Primm.

Professor E. L. Youmans, who died on January 19th, was well known as a writer on scientific subjects, the author of a work on chemistry, and the editor of the *Popular Science Monthly*. He did much to popularize scientific subjects, and was an ardent champion of the doctrines of Herbert Spencer.

Tobacco and the Centenarians.—Professor Humphrey's investigation of the physical condition and habits of centenarians shows that out of 15 males 7 smoked much, 1 smoked a little, and 7 did not smoke at all. Among 28 females, 4 smoked much, 1 a little, 1 moderately, and 22 none at all; two used snuff.

An Italian Hospital in New York.—Funds are being raised among the wealthy Italian residents of this city for the purpose of establishing a hospital for Italians.

A Remedy for Baldness is said by a correspondent of the *British Medical Journal* to be the daily use of the Granville *per cutem*.

Antifebrin in Epilepsy.—Antifebrin is being extensively used by Professor Dujardin-Beaumetz in epilepsy, on the ground that it is one of the most powerful moderators of the spinal centres. Lépine has used the same drug for the lightening of the pains of locomotor ataxia. The dose is from seven to eight grains.

Cremation in New York does not seem to have been flourishing to any great extent. There is a very fine crematory, but the New York Cremation Society has only contributed two of its members to the flames during the past year. This is not taking up the cause very warmly.

The Building of the College of Physicians and Surgeons, of this city, has been sold to an ice-cream firm, which will take possession next fall.

Prof. von Frich's Experiments with the Virus of Rabies.—The Paris correspondent of the *Lancet* writes: "The most important news of the week comes to us from Vienna, in the account of Prof. von Frich's experiments with the virus of rabies supplied to him for that purpose by M. Pasteur. M. von Frich finds: 1. That in animals which have died from rabies the virus exists in its most concentrated form in the central nervous system. 2. That small quantities of the cerebro-spinal substance of animals which have died from rabies, injected under the dura mater by trephining, are sure to be followed, after a latent period of from fourteen to twenty-one days, by the same disease, and this may be transmitted from these to other animals. 3. That the same disease, with the same symptoms and the same period of incubation, may be induced by intracranial inoculation with particles of medulla from human beings who have died of rabies, showing the identity in man and in the lower animals. 4. That infection is less sure by the subcutaneous method, and the period of incubation longer than with intracranial inoculation. 5. The length of the period of incubation depends upon the quantity of virus injected under the skin; the less the virus, the longer the incubation. 6. By the continuous intracranial transmission of the virus taken from the cerebro-spinal substance of rabbits, after a series of generations the period of incubation is shortened and its invasion is irregular. Later on the incubation still decreases, but the invasion becomes regular. 7. The *fixed virus* of an incubation period of seven days, which M. Pasteur obtains by inoculation from rabbit to rabbit through forty or fifty generations, exceeds in intensity the virus of *street rabies*, not only in that the invasion of the disease is earlier, but also because the animals die without exception as well after subcutaneous injection as with inoculation of the dura mater. 8. The fixed virus does not seem to acquire by further transmissions any noteworthy shortening of its period of incubation. Sometimes the disease begins after six days; but, on the other hand, it may extend to eight, ten, or even twelve days. An incubation period of from eight to twelve days, and consequently a virulence of the same intensity as that of the fixed virus, may also be obtained by the transmission of street rabies, and this sometimes at the second or third generation. 9. M. Pasteur's method of obtaining a fixed virus of seven days' incubation is, perhaps, not the only one, for the said virus may sometimes be obtained much earlier, independently of the transmissions, and this virus is constant in its effects and in its period of incubation. 10. The virulence of particles of medulla diminishes daily under desiccation at 20° Centigrade over caustic potash, and is entirely destroyed after from fourteen to sixteen days. 11. Animals which have been subjected to hypodermic injections of a series of virus attenuated by desiccation become refractory to the stronger virus by the previous inoculations with the weaker virus, if the stronger virus have not been used in too rapid succession. 12. Animals which have been inoculated hypodermically during ten days with virus of progressive virulence (medulla from ten days to one day) have not been refractory to infection with the fresh virus of street rabies, and have only exceptionally escaped after intracranial infection. 13. Rabbits and dogs inoculated by trephining with the virus of street rabies of sixteen days' incubation have always succumbed, notwithstanding the preventive treatment already described. 14. M. Pasteur attributed to the method of slow vaccinations the unsatisfactory results obtained previously by M. von Frich, and recommended a more intensive mode of treatment. The experiments carried out conformably to M. Pasteur's instructions have given no more favorable result; all the animals died of rabies. 15. The experiments have demonstrated a most important fact—that is, that in the rapid process the weaker preservative medullæ do not confer the same certainty of immunity from the effects of inoculation with the stronger medullæ. Of a series of dogs and rabbits inoculated as a control-experiment to that described in the preceding paragraph, and in which the rapid process was carried out without previous infection, most of the animals died of rabies. 16. Most of the animals which were submitted to the preventive treatment after subcutaneous inoculation with street rabies died of the disease even when the period of incubation was thirty-four days. These experiments show, says M. von Frich, that Pasteur's method of rendering animals refractory to rabies is not yet either sure or certain. There is not yet a sufficient scientific basis for the application in man of a preventive treatment after the bite of a rabid animal. It is, moreover, quite possible that the preventive treatment, at any rate the intensive method recently recommended by M. Pasteur, may itself transmit the disease.

Reviews and Notices.

A Reference Handbook of the Medical Sciences: Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By various writers. Illustrated by Chromolithographs and fine Wood Engravings. Edited by Albert H. Buck, M.D., New York City. Volume II. New York: William Wood & Co. 1886.

The second volume of this most complete encyclopædia of medical science embraces all the subjects occurring in alphabetical order from Catarrh to Eye, inclusive. The number of contributors to this one volume is one hundred and five, of whom thirty-four are from New York City, sixteen from Boston, seven from Cincinnati, six from Philadelphia, six from Washington, six from Baltimore, four from Montreal, three from St. Louis, three from New Orleans, three from Chicago, two from Atlanta, two from Albany, two from Brooklyn, and one each from Toronto; Auburn, N. Y.; Dayton, O.; Portland, Me.; Augusta, Ga.; Columbus, O.; Watertown, Mass.; Rochester, N. Y.; Buffalo; Charleston, S. C.; and Princeton, N. J. This is sufficient to demonstrate the truly national character of the work, and a glance at the list of names shows further that the writers of the different articles are for the most part men of more than a national reputation, and are acknowledged authorities in the various departments of medicine to which the subjects treated of by them belong.

The first article is one on Nasal Catarrh; then follow Catechu, Catoosa Springs, Caustics, Cauterets (a French mineral spring), Cauterization, Caxton Springs, Cedar Keys, Celandine, Cells, Disease of the Cellular Tissue, Cephalhæmatoma, etc. Opening the volume at random near the end, we find in regular order, Examination of Recruits, Medical Examiner (a State officer in Massachusetts, having somewhat similar functions to those of a coroner), Excelsior Springs, Neurotic Excoriations, Physical Exercise, Exophthalmic Goitre, Exostoses, Expectorants, Expectoration, Law of Expert Evidence, Principle of Extension as Employed in Surgery, Extra-Uterine Pregnancy, etc. The enumeration of these titles will suffice to show the varied character of the articles contained in the "Handbook." We find here subjects relating to medicine, surgery, obstetrics, legal medicine, health resorts, medicinal springs, materia medica, and, in fact, every branch of medical science. It is safe to say that the physician will find in this book all necessary information on any subject even remotely connected with his professional work, and what the "Encyclopædia Britannica" or Appleton's is to one in quest of information on general subjects, that will be the Reference Handbook to the physician seeking to refresh his memory or to gather new facts in his own particular field of study.

Some of the articles are veritable monographs on the subjects of which they treat, and indeed the only criticism which might be made is that they are too long. It is extremely difficult, it is true, to deal thoroughly with an important subject in a few columns or a few pages, but one does not turn to an encyclopædia with the expectation of finding there all the information that is contained in special treatises. Such a work is, or should be, a depository of facts or of the outlines of a subject, where one can find what is practically useful and no more, but which serves at the same time as a sort of index showing where the student may find, if time permits and inclination prompts, a more exhaustive presentation of the subject. It is fair to state, however, that this criticism applies to but few of the articles contained in this volume, and most of them exactly come up to our idea of what a work of this kind should be. The subject is presented briefly, but with all-sufficient thoroughness, and at the end of the article is a short bibliography containing all the latest and most important special treatises bearing on the matter under consideration. And even with the long articles we have no fault to find except on account of their length. They contain good, sound doctrine, and if one had the time at his disposal he could spend it to no better advantage than in studying them and making himself master of the subjects of which they treat.

We cannot close this brief notice without referring to the illustrations. There are over five hundred wood cuts in this volume, all of them clear and distinct. They are not thrown in hap-hazard, but have been judiciously selected, and do what illustrations, especially in medical works, do not always do—they really illustrate the text. The large majority are original, and bear about them a refreshing odor of newness. In addition to the wood-cuts, the volume contains six full-page chromolithographs, illustrating the tests for color-blindness, affections of the cornea, dactylitis syphilitica, the plant Cornus florida, Elephantiasis arabum, and the Eucalyptus globulus.

The work is to be completed in eight volumes. It is large octavo in size, beautifully printed on fine paper, and strongly bound. It is a work that commends itself alike to the busy practitioner whose time for study is limited, and to the young physician who, whatever he may himself think, is really fortunate in having many spare hours to devote to study and to a more thorough grounding of himself in the essentials of medical knowledge.

Des Cataractes et de Leurs Opérations. Conférences Cliniques, professées par le Dr. Galezowski, et recueillies par le Dr. Boucher, Médecin-major de 1re classe.—Cataracts and Cataract Operations. By Dr. Galezowski. Paris: A. Delahaye et E. Lecrosnier. 1886.

A series of five chemical lectures by Dr. Galezowski, in which the subject of the different forms of cataract, and of the operations for its cure, is treated in a lucid and instructive manner by this accomplished ophthalmologist.

The Laws of Generation, Sexuality, and Conception. By H. M. Gourrier, M.D. Translated and Edited, with an Introduction and Notes, by Franklin Duane Pierce, M.D. Union Springs, N.Y.: Hygeia Publishing Co. 1886.

In this book the author treats of the laws governing sex in generation, deriving his arguments from a study of reproduction in the lower animals as well as in man. He believes that the sex of the offspring is invariably that of the weaker parent.

The Principles and Practice of Medicine. By the late Charles Hilton Fagge, M.D., F.R.C.P., Physician to and Lecturer on Pathology at Guy's Hospital; Examiner in Medicine in the University of London; Senior Physician to the Evelina Hospital for Sick Children, etc. Including a Section on Cutaneous Diseases by P. H. Pye-Smith, M.D., F.R.C.S., Lecturer on Medicine at Guy's Hospital; Chapters on Cardiac Diseases, by Samuel Wilks, M.D., F.R.S., Physician to Guy's Hospital, and to the Royal Hospital for Children, London; and Complete Indexes, by Robert Edmund Carrington, M.D., Assistant Physician to Guy's Hospital, London. Vol. I. Philadelphia: P. Blakiston, Son & Co. 1886.

In the volume before us Dr. Fagge discusses, under the head of general morbid processes, subjects of such profound importance as contagion, fever, inflammation, tubercle, tumors, and syphilis. The specific diseases such as typhus, typhoid, scarlatina, variola, cholera, erysipelas, and diphtheria come next, and are followed by chapters on the diseases of the nervous system. Diseases of the respiratory system are then fully dealt with, asthma influenza, and whooping being arranged under the common heading of functional disorders of the respiratory organs. Of course this arrangement and classifi-

cation is open to criticism, but it should be borne in mind that at the time of the author's death his manuscript was incomplete as regards this very point. Moreover, no system of classification is perfect, and unless diseases are arranged alphabetically their grouping will always be more or less arbitrary, because reflecting the personal views of the author. If the second volume of this treatise fulfils the promise of excellence contained in the one before us, the entire work cannot fail to find favor with the profession both here and abroad.

La Goutte, sa Nature et son Traitement. Par le Dr. W. Ebstein, Professeur de Médecine et Directeur de la Clinique Médicale à l'Université de Gœttingue. Traduction du Dr. E. Chambard, Ancien Interne des Hôpitaux de Paris. Introduction du Professeur Charcot, Membre de l'Institut. · Ouvrage orné de 12 chromolithographies.—Gout, its Nature and Treatment. By Dr. W. Ebstein. Paris: J. Rothschild. 1887.

This is a French translation of Dr. Ebstein's well-known and justly prized work on the nature and treatment of gout. The author dwells principally upon the pathology and morbid anatomy of gout, though the symptomatology and treatment are by no means neglected. The theory of Ebstein concerning the local lesions of gout is, that there is first a limited necrosis of the tissues excited by the presence of acid urates, and later neutral urates are deposited at these points. The text is enriched with twelve finely executed chromolithographs. By reason of the excellent typographical execution, fine paper, and unusually substantial binding, the work before us might almost be called an *édition de luxe*.

The Curability of Insanity: A Series of Studies. By Pliny Earle, A.M., M.D., late Superintendent of the State Lunatic Hospital at Northampton, Mass. Philadelphia: J. B. Lippincott & Co., 1887. Pp. 232.

This volume is essentially the reprint of a series of papers the first of which appeared in 1876 and the last in 1885. These papers are unquestionably sound, exhibiting as they do, in the light of the best obtainable statistics, the entire subject of the curability of insanity. That the theme is important to the last degree in a country where mental disorders are ever on the increase requires no insistance. Even those who are not specially interested in psychological matters will derive much useful instruction from a perusal of this little volume.

The International Encyclopædia of Surgery: A Systematic Treatise on the Theory and Practice of Surgery by Authors of various Nations, edited by John Ashhurst, Jr., M.D., Professor of Clinical Surgery in the University of Pennsylvania. Illustrated with chromolithographs and wood-cuts. In six volumes. Vol. VI. Pp. 1272. New York: William Wood & Co. 1886.

The sixth and last volume of this great work fittingly brings to conclusion the most important surgical publication issued within the memory of the present generation of surgeons. It is not too much to say that the editor and his collaborators, both here and abroad, and that the publishers as well, have placed the profession under lasting obligations for the great care and fidelity with which they have executed their several tasks.

The present volume contains the concluding articles on the injuries and diseases of the various regions of the body, and also supplies numbers of articles necessarily omitted from previous volumes, owing to the inability of the writers to complete them in time for insertion in their appropriate places. The surgery of the alimentary canal is completed by articles on the œsophagus from the pen of Dr. J. Solis-Cohen, on intestinal obstruction by Dr. Ashhurst, and on injuries and diseases of the rectum by Dr. Allingham. Dr. Keyes contributes an elaborate article on urinary calculus, which is further supplemented by a brief special article on lithotrity from the pen of the veteran lithotritist of Montreal, Professor Hingston. Dr. Reginald Harrison discusses the surgery of the bladder and prostate, Professor Duplay, of Paris, that of the male urethra, and Mr. Royes Bell, of London, that of the male organs of generation.

The female generative apparatus is considered in three articles contributed by Drs. Parvin, R. P. Harris, and Charles C. Lee, who wrote respectively on injuries and diseases of the female genitals, Cæsarean section and allied operations, and uterine and ovarian tumors.

The remaining articles are on inflammatory affections of the bones, by Professor Ollier, of Lyons; structural diseases of the bones, by Professor Vincent, of Lyons; tumors of the bones, by Professor Poncet, also of Lyons; and a special contribution on orthopædic surgery, by Dr. F. R. Fisher, of London.

An appendix contains interesting and instructive articles on the construction and organization of hospitals, by Edward Cowles, of Somerville, Mass.; the preparations of military surgeons for field duties, including the modern system of ambulance service, by Dr. B. A. Clements, U.S.A., and a brief, yet sufficiently comprehensive, review of the history of surgery, by Dr. George J. Fisher, of Sing Sing, N. Y.

An excellent general index, prepared by Dr. H. R. Wharton, ends the volume.

A Handbook of Hygiene and Sanitary Science. By George Wilson, M.A., M.D., F.R.S.E. Sixth edition. 8vo, pp. 520. Philadelphia: Blakiston & Co. 1886.

Wilson's Handbook has achieved a decided success, and has for some time been recognized as a standard text-book. The present edition calls for no extended comment therefore, since its merits are acknowledged. The editor has added considerable material, however, and has made his book still more representative of the present state of sanitary science. The additions consist of a description of the several diseases which render the flesh of animals unfit for food, a completion of the chapter on water-analysis, a short section on sewage and effluents, a new chapter on soils and localities, a separate chapter on disinfection, besides correction and remodelling of other portions of the work.

A Treatise on Electrolysis and its Applications to Therapeutical and Surgical Treatment in Disease. By Robert Amory, A.M., M.D. (Harv.). New York: William Wood & Co. 1886. Wood's Library of Standard Medical Authors.

We welcome the publication of works tending to place the use of electricity in medicine upon a clearer and more scientific basis than that which it occupies at present. The very limited education in physics, which unfortunately too many practitioners have, as well as the progress of that science in late years, has tended to becloud the art of electro-therapeutics; and it remains, to a large extent, mere empiricism. Dr. Amory's book will be of service in giving physicians an opportunity to learn the latest views regarding many points in electro-physiology. His first chapter is devoted to a description of the nature of electrolysis, by which we understand is meant the chemical relations of electricity to the human body. The author then describes the batteries used, the laws of resistance and diffusion of electrical currents, and the methods of applying them to the body. With Chapter VI. begins the practical application of electrolysis in disease. The number of diseases for which electrochemical effects are used is now quite large. Dr. Amory describes the use of electricity in aneurisms, ulcers, tumors, Basedow's disease, hypertrichosis, urethral strictures, extra-uterine fœtation, etc. The book is illustrated with a considerable number of very excellent wood-cuts.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, January 7, 1887.

GEORGE F. SHRADY, M.D., PRESIDENT, IN THE CHAIR.

FIBROUS ANCHYLOSIS AT THE SHOULDER-JOINT—RECOVERY.

DR. V. P. GIBNEY presented a man who, without known cause, began to suffer from pains in his left shoulder. At times previous to May, 1885, he had had what he regarded as rheumatic pains. During the summer of that year the pains about the shoulder were aggravated by such movements as abduction and extension. There was no pain when the limb was at rest. The rotation was about one-half the normal, and he could abduct the arm to an angle of 45° without tilting the scapula.

Early in September Dr. Gibney put the patient under the influence of ether, moved the joint in all directions freely, and determined to employ passive motion himself daily. He continued this until September 23d, when the result was so unsatisfactory that he repeated the *brisement force* about one month later. The after-treatment in this instance consisted of rest and the application of fomentations for about ten days, when he resorted to massage and the use of the Paquelin cautery. At the end of a week the suffering of the patient had been increased, and his shoulder was much stiffer than when treatment was begun. During the next three months he did nothing in the way of treatment, suffered little or no pain, and at the end of that time his arm was more useful, the arc of motion was increased, and there was neither atrophy nor shortening, nor infiltration. Now, nearly a year after the patient first came under Dr. Gibney's observation, the functions of the shoulder were perfect, and this result was not due to any particular mode of treatment. Whether the forced movements to which Dr. Gibney subjected the patient conduced to the good result, he was unable to say.

THE PRESIDENT then read a paper [see p. 85] entitled

THE CURABILITY OF CANCER BY OPERATION.

DR. J. D. BRYANT opened the discussion, and said that he had not studied directly concerning the length of time that had elapsed between the date of the operation and the date of recurrence. It had occurred to him, however, to reason upon the subject before the Society somewhat in the following manner: Cancer is either a constitutional disease or it depends upon a constitutional condition, or else it is a local disease depending very largely upon irritating causes. He had been accustomed to regard it very much as he had tuberculosis; not exactly a local, nor precisely a constitutional disease, but rather a disease that depends upon vulnerability of the tissues, one tissue being more vulnerable than another, the uterus or breast of one woman being more exposed than that of another, or responding to irritation more readily.

But whether local or constitutional, the only rational means of effecting the cure of cancer was by operative procedure. When considering the question of treatment the inquiry should arise: How does the disease cause death? It may do so directly by its extension, or by establishing a cachexia, or by absorption of poisonous material from the growth, or by the pain and depressing influence upon the patient's mind. This view of the case should teach the surgeon to operate early, and often. He had no question but that the best results would be obtained in cancer by operating before any of the surrounding tissues became involved—even the tissues lying in contact with the mass of disease.

Moreover, antiseptic surgery, which obviates the process of suppuration, will increase the favorable results.

But the answer to the question of operative procedure varies largely according to the part of the body in which the disease is situated. He could recall three cases of malignant disease of the parotid, in two of which he felt satisfied that the length of the patients' lives would have been increased had he avoided operating for its removal; in one case, however, he was sure that life was prolonged considerably. He also referred to a case of multiple sarcoma in Bellevue Hospital, where he removed seventeen nodular masses, and prolonged the patient's life.

He had had two cases of malignant disease of the lip, on which he operated, and the disease had not yet returned, though distant four and six years respectively from the date of the operation. On the other hand, he had in mind a case in which he cut the lip away freely, and a short time after the operation the malignant disease developed in the submaxillary gland, which he removed, and soon afterwards in the opposite gland, and after the removal of the last growth the return of the disease was very rapid.

But by operating early and often and under antiseptic precautions, he believed with Dr. Shrady that the percentage of recoveries for malignant disease could be increased, and also that life could be prolonged.

DR. C. C. LEE concurred in what Dr. Bryant had said, not having had the pleasure of listening to the paper of the evening; that is to say, resort should be had to excision in cases of malignant disease under ordinary conditions, and at as early a stage as possible. In cases of disseminated cancer, it always becomes a question whether or not all the disease can be removed. In cancer of the uterus or vagina, or both, he advised early operation, except when the neighboring lymphatic glands were involved.

DR. R. F. WEIR agreed with the opinion of many that cancer is a local disease, and he looked favorably upon the theory that it was of germ origin. Entertaining these views, he could but agree with Dr. Shrady and the gentlemen who had spoken that, to obtain the best results, resort must be had to early operation. Not only should surgeons perform operations early, but they should teach their patients that they should be operated on early.

The surgeon should operate not only early, but widely from the diseased part.

Since the advent of antiseptic surgery, which permitted the surgeon to operate much more thoroughly and extensively than before its coming, statistics, amounting in the aggregate to 700 breast cases, gave a recovery, lasting more than three years, in ten per cent.

It was the fact that the surgeon could operate widely from the diseased part that had made lip-operations so satisfactory, and in six hundred cases, recovery, lasting more than three years, took place in twenty-nine per cent.

Amputation of the penis for cancer had also given good results, and so had amputation of limbs for cancerous disease.

In these four classes of cases the best results had been obtained, and the great reason was because the operations had been performed wide of the disease. But on account of anatomical reasons, it is impossible to cut wide of the disease in cancer of the tongue, etc., and this fact is the most discouraging feature of such cases.

DR. W. T. BULL was quite in accord with what had been said concerning the necessity for early, as well as very radical, operations. He had been struck by the fact that in breast cases the patients come very late indeed for operation.

He believed that exploratory incision, especially in the early stage of breast tumors, deserved more general mention and adoption than it thus far had received. Probably, in nearly fifty out of sixty cases, the tumor ex-

ists a year before going to a surgeon for advice, and all this time the case is under the observation of the general practitioner, who hesitates to recommend an operation until sure of his diagnosis, and this lapse of time is to the patient's detriment.

Dr. Bull had adopted the exploratory incision in three cases, and it had been extremely satisfactory. If the diagnosis cannot be made with the unaided eye, the microscope can be used. In cases of suspicious ulcer of the tongue, and of disease of the uterus, the exploratory incision can be very readily practised, and very much precious time in the early stage of a malignant affection be saved.

As an illustration of radical operation for cancer, he mentioned a case in which he removed the entire uterus two and a half years ago, and there had not been any recurrence of the disease. He believed that similar radical operations were not resorted to with sufficient frequency by those who perform surgical operations.

He also thought that it was rather exceptional to remove the skin thoroughly enough, and examine the axilla with sufficient care, in breast cases. With regard to the axilla, an examination of it through the skin was entirely inadequate. In every case of cancerous disease of the breast the contents of the axilla should invariably be removed as a part of the operation, and all of the adjacent tissues examined in the most thorough and extensive manner.

Dr. Weir remarked that the operation should be particularly conducted to the examination and removal of the most distant glands.

Dr. Bull further remarked that he had, during the last three years, given arsenic to nearly every patient upon whom he had operated for cancer, but had not been able to discover that it produced any effect whatever on the disease.

Dr. W. M. Polk said, concerning the use of internal remedies, that his experience coincided with Dr. Bull's. He had used various substances extensively, but without any evidence that they were beneficial.

There was one point that he had noticed in connection with operative procedure ; that is, he had occasionally seen a case of cancer of the breast, in an elderly person, that was pursuing a slow course, had been in existence several years, and that without producing a very threatening effect upon the general health of the patient, but in which an operation had seemed to act as a stimulant, and immediately thereafter the disease had progressed rapidly to a fatal termination.

With regard to operation for cancer of the uterus, surgeons had been deterred from operating widely on account of the liability of encountering the ureters. He had operated in six cases, and had become satisfied that he would have done better had he gone further into the surrounding tissues than he did. In one case he demonstrated that he could have gone safely three-fourths of an inch upon each side further into the surrounding parts, and hereafter he should feel disposed to be somewhat bolder in this respect than he had been heretofore.

Dr. A. H. Smith had had the case of a woman, sixty or seventy years of age, under observation nearly three years, where the question of operation had been constantly pressing upon him. The disease in the breast had progressed exceedingly slow, and there apparently remained a chance of the patient getting a number of years of life. He thought it was probable that the result would have been different had the patient been operated upon. The disease began at about the age of sixty.

Dr. Bull said it was a generally recognized fact that scirrhus beginning at that time of life had better be let alone.

Dr. Samuel Sexton had, at one time, been specially interested in examining proofs of death in cases of life insurance, and had noticed that in nearly all cases of death from cancer there had been the history of one or more deaths from consumption in the family.

Dr. W. M. Carpenter spoke on invitation, and said that the case mentioned by Dr. Smith brought to his mind one that he saw with an eminent surgeon in London, who advised extirpation, and then turned and asked if that was not good surgery, and if it was not what New York surgeons would advise. The answer was that, to the best of his knowledge at that time, an operation would not be advised by most New York surgeons, and that it would not be regarded as good surgery to operate in such cases. The patient was a thin old woman, who had a flat tumor in one of her breasts that was not giving rise to any symptoms, and had progressed so slowly that several years had been consumed in reaching its present condition.

Dr. Carpenter also referred to a case which he saw in consultation, and assisted at the operation for removal of the cancerous breast July 29, 1876. The specimen was examined microscopically by Dr. Francis Delafield, who diagnosticated cancer beginning in the milk-ducts. The nodule was about an inch and a half in diameter, was painful and increasing in size, was not attached to the skin, and there were no enlarged glands, although at the operation several axillary glands were removed. The patient was about forty years old, and is still living, and in the enjoyment of her usual degree of health.

On the other hand, he saw in August last a patient, much enfeebled in health, about forty years of age, who had a lump in one of her breasts, about an inch in diameter, that had remained stationary for about two months. She was told not to give herself any anxiety concerning it ; but her friends were told to watch it with the utmost care. It was not attached to the skin ; there were no glandular enlargements that could be detected, and it had not been painful.. The patient was advised to let the nodule completely alone, and to make sure that it was not pressed upon by her clothes. At the end of three months the report was that it had disappeared entirely.

The occasional occurrence of such cases doubtless had contributed much toward causing patients to postpone seeking surgical advice, and also had deterred many surgeons from operating as early as they should have done.

He regarded it as safest for the patient, however, to advise the earliest possible and most thorough ablation of every breast that contained a suspicious new-growth, which began at an age under sixty years.

To illustrate the necessity of operating widely, he referred to a case in which he examined microscopically a breast that was removed by Dr. T. M. Markoe. A little oblong body at considerable distance from the breast was selected, with other portions, on the supposition that it was an enlarged lymphatic gland. On examination of the sections, however, it was found that it was only a lobule of fat, but in the meshes of it could be seen distinctly occasional cells that presented the same appearance as those found in the alveoli in the cancerous mass in the breast.

Dr. Shrady, in closing the discussion, said that the main object of his paper was to enforce the necessity of early operation in cancer, and to persuade general practitioners to consult surgeons in such cases early enough to give the patient the best possible chance to get cured. Of course, it should be taken for granted that he would operate, not only as early, but as widely as possible, and he would remove all adjacent glands, even though they might be apparently healthy. With reference to the dissemination of cancer, he was in the habit, several years ago, of taking sections from specimens presented at the New York Pathological Society, and examining them with the microscope, and often at the edges of the incision he had found cancer-cells in an active state of proliferation and nests that had been cut through. Of course the results after these operations could not be compared with what could now be obtained in the same class of cases.

He had not said anything concerning the use of caustics, because they are useful chiefly in cases of superficial cancer, and also because it was his purpose to speak of operative procedures chiefly. Similar remarks were applicable to the use of internal remedies. He had used arsenic, but without special benefit. The best effects after operations had been produced by giving tonics.

Dr. R. F. Weir then read a paper (see p. 88) on

A NEW METHOD FOR DETERMINING WHETHER OR NOT RUPTURE OF THE BLADDER HAS OCCURRED.

Dr. E. D. Hudson, Jr., presented

A VERY LARGE-SIZED GALL-STONE,

removed, post-mortem, by Dr. Satterthwaite from the jejunum of the late Dr. Darken, who died with well-marked, although at no time violent, symptoms of intestinal obstruction. His abdomen was not distended, nor was it tender on palpation. He had never had an attack of jaundice or biliary colic. The calculus was so large that it occluded the gut entirely. On examination of the gall-bladder it was evident from its thickened walls and pouch-like formation, and also the configuration of the calculus, that the stone had occupied this cavity, and that ulceration at the most dependent portion of the bladder had taken place, which allowed the large body to escape into the duodenum, from whence it passed onward and produced complete obstruction in the jejunum. The liver was apparently normal. Dr. Hudson thought this was an instance in which surgery might have saved the patient.

FATAL INTESTINAL OBSTRUCTION FROM A GALL-STONE.

Dr. W. T. Bull presented a similar specimen, which measured in its three diameters 7.84, 4.3, and 3.9 centimetres and weighed sixty grammes. It was composed of cholesterine and bile-pigment, with a thin crust of lime salts. No nucleus was seen, but the material was concentrically arranged. It was presented to him by Dr. Frank W. Murray, of New York, who saw the patient twenty-four hours before death. The patient, a man seventy-eight years of age, who died after six days' illness, characterized by constant vomiting of dark-green fluid without marked pain or abdominal swelling or tenderness. On the day before death Dr. Murray felt distinctly a freely movable tumor just below the umbilicus, but the general condition of the patient forbade an exploration. Twice during the illness the bowels responded to cathartics. The stone was found firmly impacted in the ileum about three feet from the ileo-cæcal valve. Ten years before death the patient was ill three weeks with vomiting, pain in the stomach and right side of the abdomen, and jaundice, and several similar but less severe attacks occurred subsequently.

The specimen was of interest on account of its size, and the fact that it formed a tumor appreciable to touch—a fact which has not been observed in other cases, according to Treves. Had it been discovered earlier it could have been removed by a simple operation, and the obstruction relieved. Only a hasty examination was possible, and the gall-bladder was not examined, but probably would have shown signs of the ulcerative process by which these stones usually escape into the duodenum.

In a recent article on the subject by Wising (referred to in the *Medical News*, October 9, 1886), the writer analyzes 51 cases, of which 38 ended fatally. In only 5 cases was a tumor perceptible. Laparotomy was performed in 4 cases with fatal result. In the same number of the journal Evans reports a case in which a calculus two and a half inches long was passed after inflating the bowel for twenty minutes.

Dr. Hudson mentioned a case in which there was a history of repeated attacks of hepatic colic, and Dr. Wylie made an exploratory incision, but no gall-stones were found. He also presented two specimens of what Murchison had named

PEPPERCORN GALL-STONES.

They were removed from the bodies of patients who died at the Colored Home, and no well-formed calculi were found other than these exceedingly small ones, of which there was a very large number. Murchison had suggested that these fine calculi probably came from the hepatic duct.

The Society then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE HARVEIAN LECTURES ON CANCER OF THE UTERUS—THE TREATMENT OF MENTAL DISEASES—PARISH INFIRMARIES AS FIELDS OF CLINICAL STUDY—THE DEGREE QUESTION.

London, January 4, 1887.

Dr. John Williams, in his recent Harveian Lectures on "Cancer of the Uterus," ran counter to some commonly received doctrines. Dividing the uterus into three parts, viz.: (1) the vaginal portion, (2) the cervix proper, (3) the body and fundus, he premised that, by cancer of any one of these parts, he meant cancer originating in that part, and not cancer invading it from another source. Cancer of the vaginal portion was then considered in detail. Injury to the cervix has been by many considered as a frequent precursor of malignant disease in that part, and as disposing to it. Erosion, it has been thought, might, in subjects predisposed to malignant disease, eventually become cancerous in nature. The researches of Ruge and Veit have been regarded as confirming this conclusion. Dr. John Williams, however, maintained that there was no evidence that, so far as regarded cancer of the vaginal portion, laceration played any part in its causation. He had never found it to start from a a tear of the cervix. Neither did he think child-bearing had much to do with the disease. Out of eight cases five had had less than the average number of children, and in no one had labor been severe. In three cases the patients had had no children. He remarked that the cancerous portio vaginalis might be quite smooth and seem fairly healthy, with perhaps slight lividity of the surface. It might, on the other hand, be papillary, tuberculated, or granular. In three cases there was simply enlargement of the lips.

Why should not mental diseases be treated at our general hospitals? Such is the plea put forward by a well-known alienist, Dr. Rayner, in a recent number of *The Times*. Such a plan is doubtless beset with difficulties, but these are not insuperable, and the adoption of it would remove a blot from our present treatment of the insane. In many of our large public asylums, probably, much is done to ameliorate the condition of the patients, and a certain proportion of the inmates are, after a stay of varying length, discharged as cured. Can as much be said for our private asylums? The private asylum system offers no inducement whatever to the physician in charge to endeavor to effect cures. He is generally either the proprietor, or has at least a share in the institution. It is therefore to his pecuniary interest to receive as many patients as he can, and to keep them as long as he can. As a sagacious mental attendant remarked to me a month or two ago, the removal from a large asylum of a private patient, whose relatives are paying four or five hundred pounds a year for him, means the loss of a sum sufficient to pay the butcher's bill. Under such circumstances, he remarked, was it likely the doctor would lose a patient if he could help it? Obviously not. The private asylum system in England is virtually doomed. Although the abuses and

cruelties of a by-gone generation have been removed, and the proprietors and physicians of private asylums are mostly educated and humane men, still they can't be expected to take a keen interest in "treatment," which, if successful, will empty their establishments and deplete their pockets. It has been wisely said that all private asylums should be converted into public institutions, and a resident physician appointed to each at a liberal salary, fixed independently of the number of inmates. Then, and only then, can scientific treatment of the insane be expected on an adequate scale. A medical man who is also a part proprietor of the asylum can scarcely, however disinterested he may be, give the same time and attention to the subject as one in the position indicated.

Another subject which has again been to the fore, of late, is the utilization of the vast amount of clinical material at present running to waste in our workhouse infirmaries. This desirable result has been brought about in one of the metropolitan parish infirmaries. At the Paddington Infirmary, during the autumn months, the wards were thrown open to the students of St. Mary's Hospital, while the latter institution was temporarily closed for repairs. Some members of the hospital staff also attended at the infirmary to give clinical instruction. In most London parishes the infirmary is now a distinct building from the workhouse, and is in many cases an imposing edifice of brick and stone, rivalling in magnitude some of the large hospitals. With regard to the sanitary arrangements, those of the parish infirmaries are superior to many of those in hospitals, as the former buildings have in many cases the advantage of being modern and constructed in accordance with approved ideas of sanitation. It is easy to understand that in an infirmary containing from three to four hundred in-patients, much clinical material of value is to be found. But before this can be utilized, leave must be obtained from the "guardians of the poor." I know of at least one parochial infirmary, where the resident medical superintendent was anxious to utilize the clinical material at hand for teaching purposes, but the guardians ruthlessly put a stop to his plans.

The movement in favor of the two colleges obtaining powers to grant a degree, gathers head. At the adjourned meeting, at the College of Physicians, very decided progress was made, and a resolution, "that an application be made to the Crown by the Royal College of Physicians of London, and the Royal College of Surgeons of England, acting conjointly, for power to confer degrees in medicine and surgery," was carried without a dissentient. Professor Latham, of Cambridge, acknowledged his conversion to the scheme, among the supporters of which, at the recent meeting, were also to be found Dr. Priestley and Sir William Gull. The latter coolly proposed that the new degree should be called M.D. Lond., and that the graduates of the present university in London should rename their degree, M.D. Univ. Lond. We have heard of M.D. Albert University, and of M.D. Westminster, but to deliberately appropriate the title now given by another university is a piece of audacity worthy only of Sir William Gull.

INTUBATION OF THE LARYNX.

To the Editor of The Medical Record.

Sir: Dr. Northrup's article in The Medical Record of December 11, 1886, on "Laryngeal Diphtheria, Intubation," etc., contains statements that suggested the following questions, which the writer hopes may prove pertinent. They are asked in a genuine spirit of inquiry, and are not polemic, in so far as intention goes, at least.

Dr. Northrup, in his record of post-mortems, neglects, for the most part, to mention whether the subjects had died after intubation.

As his article stands, information on this point is apparently lacking—only mentioning the obductions of seven infants, on whom he himself had performed intubation.

Now, with intubation the average physician would naturally fear that aliment taken into the mouth and attempted to be swallowed, or the stomach's contents, through vomiting, would be in danger of gaining access, through the tube, to the middle and lower air-passages. In case this happened, what would be the result? Orth says, speaking of suppurative pneumonia: "The severest type of this inflammation is that produced by the aspiration of food, vomit, blood, etc.—the so-called 'schluck pneumonia,' *i.e.*, gulped or swallowed pneumonia. It is, in its nature, a catarrhal broncho-pneumonia; but the exciting cause may and does occasion a malignant or septic form of this disease. Yes, under certain conditions, it may become gangrene—gangrena diffusa. The presence of food in the bronchi one may easily recognize with the naked eye, or by the sour smell of vomit. A certain result is likewise given by a microscopic examination of the bronchial and alveolar contents" (Orth's Comp. der Path.-Anat., Diagnostic seite, 214). Had Dr. Northrup explained whether or not the conditions described above had been found, would it not have settled a very grave doubt in the minds of some of the gentlemen who read his article? Next, how do large plaques of exfoliated membrane escape through the tube? What does Dr. Northrup say of this? Scarcely anything. In one place, he speaks of a large membrane engaging the lower aperture of the tube, and the expiratory efforts causing it to be projected across the room. In another place, he says: "You may think best to remove the tube at some time, because the child *swallows badly*, or because it secretes an unusual amount of tenacious mucus, or because, for any reason, you desire to give it a good opportunity to use its larynx to give more explosive force to the cough. The chances are that as you remove it, there will follow a large piece of false membrane, or a quantity of mucus, and you will be pleased at your judgment in advising it." This is about all he does say on this point. The question still maintains, How can a mass of exfoliated membrane pass this artificial mediate that would possibly occlude the normal larynx itself? The following annulæ ○ ○ represent the normal calibre of the largest and smallest sizes, respectively 12 years to 1 year of O'Dwyer's tubes, a light glance at which must make one sceptical as to the possibility of a large exfoliated placque of pseudo-membrane gaining exit through even the larger, to say nothing of the smaller one. Dr. Northrup himself asserts that it takes more time and skill to remove the tube than it does to insert it. In case a blockage occurred, would not the patient's life be seriously threatened, before the tube could be removed, under the most favorable circumstances? And suppose there was no skilled one near to remove the tube?

Surely, none can say that tubage offers the certain exit of compromising materials that the tracheal section gives; and the technique of this operation has been improved to meet almost any emergency in this line. In regard to his statistics, there are 165 cases quoted as intubated—twenty-eight and one-half per cent. recovering.

No information is given in regard to the character of the respiratory ailment in the larger number of these cases. True, from the caption of his article, one may (*cum grano salis*) suppose they had laryngeal diphtheria, but the diversified character, both of his information and the general dissonance of opinion on the subject of diphtheria and membranous croup, makes the doubt of them all being bona fide cases of diphtheria a serious question. Admitting they were, still it would not immeasurably eclipse the results of tracheotomy. Henoch, out of 66 cases of laryngeal diphtheria, saved by tracheotomy 16—a per cent. of $24\frac{8}{33}$; and, he apologizes for the mortality by stating that they were hospital cases. As far as authenticity is concerned, comment is superfluous.

Dr. Northrup, in one section of his article, upon his

own authority, makes the statement "that there is never any ulceration of the cords; but slight ulceration may be produced by the head and lower end of the tube, when retained for a long time. *This can do no harm.* Koenig thinks it necessary to say considerable on the subject of these self-same ulcers that *can do no harm.* He says: "Little children are especially in danger from this so-called 'ulcus decubitus trachealis;' and since it happened to me that a child which had recovered from diphtheria died of a lethal hæmorrhage into the trachea from such an ulcer, since that, I say, I am always fearful of this complication. The most prominent symptoms of this trouble are the occurrence, in the later stages, of renewed small hæmorrhages, renewal of fever, and the acquirement of an unhealthy appearance in the tracheal wound." Again, he speaks of little tumors that appear on the mucous membrane of the larynx and trachea, following cannulization of the trachea. Of these, "they are small granulation tumors—true granuloma." Their history is still somewhat new, and their mention in literature is small. Koch has collected from literature 26 cases; outside of this, there might be mentioned a dozen observations. But if one should conclude that this number represents its real frequency, then one would certainly reckon widely too little.

We believe that there scarcely exists a surgeon, who has had many tracheotomies who has not had one or more such cases. Whether it was recognized or not, is another question. He further says that these tumors are likely to appear anywhere that the tube has exercised the least pressure, and calls attention to von Trendelenberg's observation of the tendency of the mucous membrane of the trachea and larynx to take on a granular inflammation, —particularly the membrane within the thyroid and cricoid cartilages. "These granulomes are of various forms and conditions, sometimes pedunculated in form of polypi; again, warty or velvety, and spread over much surface. They sometimes appear early in the case (five days, Körte), generally later, ten to fourteen days; and it seems that the longer the cannula remains, the greater is the disposition for their recurrence. Or they may not appear until long after the tracheal wound is healed, and produce a chronic 'status asphyxiosus.' Koenig lost a patient from this cause three years after it had recovered from a tracheotomy" (Koenig, "Spec. Chir.," s. 695 u. 699). True, the sophism may be produced that all of this comes of the tracheal tubage, and not of the laryngeal; but the gentleman *does mention* that ulceration *has occurred*, even in the small number of cases now on record. Mark the insidious dangers that Koenig attributes to these ulcers that "*can do no harm.*" Ditto, the tendency of the mucosa of larynx and trachea, by pressure of foreign bodies, to take on a granular degeneration process (von Trendelenberg). Also Dr. Northrup recommends the largest tube that can be conveniently inserted.

I will not allude to other pros and cons that would only be prolix and unique, but hasten to the doctor's question: "Now, does it leave the patient without any of the advantages offered by tracheotomy?" It is to be regretted that the doctor did not attempt to establish limitations for the measure, instead of factoring dogmas of inquiry. For a true friend to the operation can but see injury in a too enthusiastic advocacy of it. Physicians, with all degrees of ability, will rush in, believing and promising all, and, because it does not accomplish all, will not recognize or be grateful for the good it may do—they eventually becoming sceptical, even enemies of the measure.

In fact, from the commotion and favor it is occasioning, both among the laity and profession, you may have a repetition of some such inglorious failure as that which happened in the early history of the transfusion of blood. "For when blood was first transfused from animals, the enthusiasm of its reception was indescribable. The tuberculous should be immeasurably improved, the transfunded one would be given new life, and be converted to the bliss of health. In time of war, herds of sheep should follow the army for the certain weal of the wounded; but too soon came the truth, and the good with the bad went to the ground, in status exodus lethalis" (Albert R. von Mosetig-Moorhof).

Dr. Northrup's anatomy, pathology, technique, and clinical history are certainly excellent, and should deserve him a place in the history of the operation. "Do you, however, if you will be persuaded by me, pay little attention to Socrates, but much more to the truth—taking good care that in his zeal he does not deceive both himself and you, and, like a bee, depart, leaving his sting behind."

Closing, I modestly mention a few suggestions. Carl Hueter says it is much easier to reach the laryngeal orifice of young children than of older ones, by reason of the very short distance between the oral and laryngeal openings of the first. I think the tube might possibly be used, instead of von Trendelenberg's apparatus, in large operations in the upper air-passages, by connecting a soft-rubber tube above the shoulder of the incubating tube—the rubber tube extending out through the mouth, and to the end of which Trendelenberg's inhaler or Junker's apparatus might be attached, and against the possibility of blood entering the trachea between the tube and larynx a cotton tamponade could be placed, after the method of Czerny.

Another use which might be made of it would be that of a guide for the various trocar instruments, such as Hanke's, used for quick and bloodless tracheotomies, or paracentesis trachealis. It would probably do away with the two greatest dangers of that class of instruments—*i.e.*, the danger of the instrument gliding into the paratracheal region, or the greater one, of the point of the instrument by pressure approximating the anterior wall of the trachea to the posterior, thereby penetrating both, and wounding the œsophagus—an almost certain result in the tender, flexible tracheas of infants; also avoiding the danger of pushing before the instrument the loosened mucus or false membranes, and thus forming a valve that would obstruct the breathing. All this looks as if it might be prevented by passing the point of the instrument down on the intubator tube.

Respectfully submitted,

A. R. JENKINS, M.D.

HENDERSON, KY., December 22, 1886.

SOME FURTHER POINTS CONCERNING INTUBATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Please permit me, through the columns of THE RECORD, to suggest to those who are about to purchase an intubating apparatus, and others who have one and who have not had any practice with it, that the much-abused common yellow dog—young one—if good for nothing else, is an excellent subject to practice on. For several reasons which are very apparent, he makes a better subject that the cadaver. He will be all the more servicable if etherized. A block of wood will answer for a mouth-gag. Some practice upon either of the above subjects should be had before attempting intubation upon a child.

BUCHANAN KLOPHEL, M.D.

MEMPHIS, TENN.

CONGENITAL ABNORMAL ANUS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In THE MEDICAL RECORD of the 25th inst., p. 707, under the head, "A Curious Malformation of the Rectum," is a communication from Dr. Frederick T. Simpson, of Hartford, Conn., who writes: "A variety of malformation of the rectum, not described by Holmes, Gross, Erichsen, or other authors, so far as I have read, has recently come under my observation. It consisted in a prolongation of the rectum, beyond its usual termination at the anus, across the perineum to the posterior

border of the scrotum. It was attached by its upper surface to the median raphé, and presented a small orifice at its termination, through which meconium escaped in small quantities. by dint of considerable straining on the part of the child." The interesting case of Dr. Simpson, described above, is, however, neither unique nor rare, as I will proceed to show. It belongs to the fifth species of the congenital malformations of the rectum and anus, according to my classification of them. In my treatise on these congenital defects, published by Samuel S. & William Wood in 1860, p. 53, I define the fifth species as follows: "In this species the rectum terminates externally by an abnormal anus, located in some unnatural situation, as at some point in the sacral region, or the rectum is prolonged in the form of a fistulous sinus, or pipe-like passage, and terminates by an abnormal anus at the glans penis, the labia pudendi, or at different points in the perineum. The natural anus being absent, its functions are more or less imperfectly performed by the abnormal one."

I also, on page 200 of the same work, make the following remarks: "These adventitious canals of the rectum differ from the ordinary fistulous passages only by being more perfectly organized, and by being entirely free from induration. They remind me very much of the fistulous sinus which the rectum, in order to relieve itself, sometimes sends off from beyond a permanent stricture of that intestine when the contraction exists a few inches above the anus. They may be regarded in the character of supplementary conduits, and cannot be considered as either an arrest of development, or as an excess of development, but as a purely pathological formation."

The treatment of this species of malformation consists in either establishing an artificial anus, in the natural situation, or of enlarging the abnormal outlet, if sufficiently near the normal site of the anus. The treatment is simple enough, and most always attended with success, provided the other requisites of life are present.

I have recorded thirty-six cases of the fifth species, and those from among them which are similar to and most resemble the case of Dr. Simpson are the following:

Durr, a physician of Augsburg in 1668, relates the case of a male child brought to him, having an imperforate anus, in which the membrane that closed the anus was prolonged forward to the anterior part of the perineum, in which was a small opening through which the meconium was drained off. He incised this membrane up to the natural place of the anus, and ultimately completed the cure.

Dieffenbach, in 1845, observed this elongation of the rectum in two male children. In one the small opening was formed in the posterior part of the scrotum.

Friedberg, of Berlin, in 1852, reports an interesting case of a male child with an imperforate anus, with a small opening in the posterior wall of the scrotum, and through which a little meconium passed when the child made violent straining efforts. Mr. Holmes, one of Dr. Simpson's authors, in his valuable work on the "Surgical Treatment of the Diseases of Infancy and Childhood," p. 168, refers to my report of this very case of Friedberg. These cases will all be found reported in full in the sixth chapter of my treatise previously named.

A similar case to Dr. Simpson's was communicated to me in a letter in July, 1861, by Dr. R. G. Levis, Surgeon to the Philadelphia Hospital, on which he operated successfully.

Mr. Green, in the "Indian Annals of Medical Science," vol. v., reports the case of a male child, presenting an imperforate anus, with an abnormal opening in the perineum, just behind the scrotum.

Mr. Goyrand reports two interesting cases of this species in *Gazette Médicale de Paris*, tome xi., p. 510, 1856.

Mr. Curling names several cases of this species in his valuable article on "The Congenital Imperfections of the Rectum," in the "Medico-Chirurgical Transactions," vol. xxv., p. 271, London, 1860.

Mr. Cripps also reports cases of this species in an able production on "The Imperforate Rectum and Anus in Infants," in "Saint Bartholomew's Hospital Reports," vol. xviii., p. 65, London, 1882.

I will close by presenting the following summary, which will give the number of cases, and other particulars of this species, as recorded by me:

Cases, 36 (males, 14; females. 13; sex not given, 9); treated, 24; successful, 21; unsuccessful, 3; not treated, 12.

Yours, etc.,

WILLIAM BODENHAMER, M.D.

249 MADISON AVENUE, NEW YORK, December 30, 1886.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 9 to January 15, 1887.

BAILY, JOS. C., Lieutenant-Colonel and Assistant Medical Purveyor. Ordered from Department of the East to New York City, to take charge of the Medical Purveying Depôt in that city, relieving Captain Henry Johnson, Medical Storekeeper, from duty as acting Assistant Medical Purveyor. S. O. 9, A. G. O., January 12, 1887.

BROWN, HARVEY E., Major and Surgeon. Granted leave of absence for six months on surgeon's certificate of disability, with permission to leave the Division of the Missouri. S. O. 9, A. G. O., January 12, 1887.

CORSON, J. K., Captain and Assistant Surgeon. Ordered to Fort Cœur d'Alène, I. T. S. O. 227, Department of Colorado, December 31, 1886.

MUNN, C. E., Captain and Assistant Surgeon. Ordered to Fort Canby, W. T. S. O. 227, Department of Colorado, December 31, 1886.

BANISTER, J. M., First Lieutenant and Assistant Surgeon. Ordered to Fort Cœur d'Alène, I. T. S. O. 227, Department of Colorado, December 31, 1886.

BARNETT, RICHARDS, Captain and Assistant Surgeon. Leave of absence further extended six months on account of sickness. S. O. 9, A. G. O., January 12, 1887.

WILSON, GEO. F., First Lieutenant and Assistant Surgeon. Leave of absence extended twenty days. S. O. 9, A. G. O., January 12, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 15, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	12	8
Scarlet fever	45	6
Cerebro-spinal meningitis	6	6
Measles	641	72
Diphtheria	111	41
Small-pox	5	0
Yellow fever	0	0

MEDICAL SOCIETY OF THE STATE OF NEW YORK.—The following are some of the papers to be read at the next annual meeting of the Society, to be held in Albany, February 1st, 2d, and 3d: "A Plea for the Intra-uterine Medication," by Paul F. Mundé, M.D., of New York; "Separation and Displacement of the Upper Epiphysis of the Humerus in a Child two weeks old, caused by Violence," by William C. Wey, M.D., of Elmira; "Par-

oxysmal Cardiac Dyspnœa," by A. L. Loomis, M.D., of New York; "The Radical Cure of Reducible and Irreducible Herniæ, touching on the Advantage of the High Removal of the Sac and the Wound being Dressed openly to Secure a firm compressive Cicatrix," by R. F. Weir, M.D., of New York (discussion to be opened by A. Vander Veer, M.D.); "Observations on Reflex Nervous Disturbances," by W. E. Ford, M.D., of Utica; "The Influence of Small Doses of Salts of Lime and Potash on Muscle, Cardiac and Skeletal," by Sidney Ringer, M.D., of London, honorary member of the Society; "Is the Danger of Post-partum Hemorrhage increased by the Use of Anæsthetics during Parturition?" and "Remarks on Antiseptic Midwifery," by Fordyce Barker, M.D., of New York; "Remarks on the Indiscriminate Use of Pessaries," by J. W. Whitbeck, M.D., of Rochester; "The Therapeutic Uses of Bismuth," by F. A. Castle, M.D., of New York; "Is Modern Midwifery Meddlesome?" by David Little, M.D., of Rochester; "Some Important Points in the Management of Deep Urethral Stricture," by F. N. Otis, M.D., of New York; "Necessity for Complete Removal of Uterine Appendages whenever Operation is Called for," by A. Vander Veer, M.D., of Albany (discussion by Mr. Lawson Tait, F.R.C.S., honorary member of the Society, of London; and by W. Gill Wylie, M.D.); "Treatment of Membranous Croup" and "Peritonitis of the Infant," by A. Jacobi, M.D., of New York; "The Clinical Significance of Cardiac Murmurs," by Wesley M. Carpenter, M.D., of New York (discussion to be opened by A. L. Loomis, M.D.); "On a Case of Dislocation of the Head of the Left Femur under the Pubic Arch," by J. S. Wight, M.D., of Brooklyn; "On the Supposed Virus of the Chancroid," by F. R. Sturgis, M.D., of New York (discussion to be opened by F. N. Otis, M.D.); "Correction of the Deformity termed Pug-nose by a Simple Operation," by John O. Roe, M.D., of Rochester; "Surgery of the Lungs," by Roswell Park, M.D., of Buffalo (discussion to be opened by R. F. Weir, M.D.); (Subject to be announced), by C. R. Agnew, M.D., of New York; "Cascara Sagrada," by A. Hutchins, M.D., of Brooklyn; "Intubation of the Larynx," by E. L. Partridge, M.D., of New York; "Demonstration on the Cadaver of the Method of Intubation of the Larynx," by J. O'Dwyer, M.D., of New York; "An Unusual Method of ridding the Male Bladder of Small Calculi—with Case," by A. Dann, M.D., of Rochester; "The Duty of the Medical Profession in Promoting Cremation," by Sir T. Spencer Wells (honorary member of the Society), of London (discussion to be opened by A. Jacobi, M.D.); "Diagnostic Areas of the Human Chest," by J. R. Leaming, M.D., of New York; (Subject to be announced), by Alfred Mercer, M.D., of Syracuse; "Tobacco Amblyopia," by H. Bendell, M.D., of Albany (discussion to be opened by D. B. St. John Roosa, M.D.); "Practical Observations on Abdominal Surgery," by W. Gill Wylie, M.D., of New York; "Irregularities of Septum Narium as an Etiological Factor in Nasal Catarrh," by F. W. Hinkel, M.D., of Buffalo; (Subject to be announced), by George H. Fox, M.D., of New York; "The Duration of the Syphilogenic Capacity in Relation to Marriage," by P. A. Morrow, M.D., of New York; "The Management of Certain Forms of Varo-equinus," by A. M. Phelps, M.D., of Chateaugay (discussion to be opened by V. P. Gibney, M.D.); "An Unusual Form of Diphtheritic Paralysis," by Laurence Johnson, M.D., of New York; "The Palliative Treatment of Cancer of the Uterus in its Later Stages," by A. F. Currier, M.D., of New York; "Perineorrhaphy," by W. W. Potter, M.D., of Buffalo; "Physiology of Menstruation," by Bache McE. Emmet, M.D., of New York; (Subject to be announced), by William Hailes, M.D., of Albany; "External Urethrotomy," by L. B. Bangs, M.D., of New York; "The Intoxicant Habit," by H. R. Hopkins, M.D., of Buffalo (discussion to be opened by William C. Wey, M.D.); "Transfusion of Saline and Saccharine Solutions in Cases of Extreme Exhaustion," by Joseph W. Howe, M.D., of New York; "Some Points of Medico-legal Interest in the Scientific Investigation of the Case of the People *vs.* Roxalana Druse, together with an Exhibition of Specimens representing the *Corpus Delicti*," by A. Walter Suiter, M.D., of Herkimer; "Questions in Nutrition," by E. V. Stoddard, M.D., of Rochester; "A Plea for a More Careful Investigation of the Urine in Infants and Young Children," by L. E. Holt, M.D., of New York; "Tests for an Antiseptic" and "Two Cases of Transplantation without Pedicle from Arm to Eyelid," by Lucien Howe, M.D., of Buffalo; "Report on Ninth and Tenth Series of One Hundred Consecutive Cataract Extractions performed according to Von Graefe's Method," by H. Knapp, M.D., of New York; "Details of Antiseptic Treatment in Emergencies and Private Practice, with Practical Demonstration of Methods," by A. G. Gerster, M.D., of New York; "The Relation of Laryngeal to Pulmonary Phthisis and the Importance of Local Treatment," by C. C. Rice, M.D., of New York; "The Obstetrical Experience of a Country Practitioner," by J. V. Kendall, M.D., of Baldwinsville; (Subject to be announced), by L. Duncan Bulkley, M.D., of New York; "A New Means of Treatment of Disease of the Frontal Sinus," by D. H. Goodwillie, M.D., of New York. The preceding list comprises all of the papers offered for the meeting up to January 7th. It is probable that other valuable articles will be presented. A resolution will be introduced at the opening session, limiting readers of papers to twenty minutes. When in excess of this time, articles should be read in abstract. Many readers fail to impress the Society, because they are unfamiliar with their manuscripts, or cannot be heard except by a few of the members present. The following gentlemen have been selected to act as the Business Committee of the Society: F. A. Castle, M.D., 55 East Fifty-second Street, New York; Laurence Johnson, M.D., 363 West Twenty-eighth Street, New York; Archibald Dann, M.D., Rochester. For information about the foregoing papers, or others not yet announced, address the Chairman of the Business Committee. All physicians wishing to attend the meeting of the New York State Medical Society, to be held at Albany, February 1st, 2d, and 3d, are informed that the New York Central Railroad Company have kindly consented to issue excursion tickets at the rate of a fare and a half, $4.65, the regular rate being $6.20. It is the intention of the majority of the delegation to go to Albany, January 31st, at 3.30 P.M. If a sufficient number can be obtained for that train a drawing-room car will be furnished for their exclusive use. Drawing-room fare, $1. All gentlemen who can arrange to go on that day and train are asked to notify the Secretary of the Delegation, Dr. Clarence C. Rice, 115 East Eighteenth Street, on or before January 25, 1887. Certificates for tickets can also be had by application to him.

War as a Therapeutic Agent.—Montaigne relates that Jason Phereus, being given up by his physicians for an abscess in his chest, and wishing to make an end of his life, threw himself headlong into a battle in the midst of his enemies. He received a wound through the body which emptied his abscess, so that it healed and he recovered.

The Best Way for the Doctor to Prove his Skill.—A writer in London *Truth* says: "A doctor may very easily make a fair reputation and a good deal of money without much knowledge of medicine; for this reason, that the science of medicine is a closed book to the vulgar. When a man dies, none of his friends (unless there chance to be a coroner's inquest) know in the least degree what killed him. And if you call in some great medical gun at the last moment, the great medical gun is sure (indeed, I believe by the etiquette of the profession he is bound) to tell you that your doctor has 'treated the case most judiciously.' On the other hand,

when a sick man gets well, no one knows what cured him, and the doctor—who was, perhaps, on the wrong track throughout—gets all the credit. Thus, the best—indeed, almost the only—way in which a doctor can convince his patients that he is wise and knowing in his profession, is by showing them that he is a clever and well-informed man out of his profession. Of his science as a doctor they are not in a position to judge; but if he talks sensibly about subjects which they do understand—stocks and shares, and pictures, and last night's debate in Parliament, and has fair luck with his cases—then his patients will trust and swear by him. I remember one very sad illustration of the injury which a doctor does himself who drops behind in his general information."

The Difference Between American and German Scientists' Meetings.—At the monthly meeting of the Society of Natural Sciences, held at the Buffalo Medical College Building recently, Dr. Julius Pohlman read a paper on the German Association of Naturalists and Physicians, to the meeting of which at Berlin he was sent by the American Association for the Advancement of Science, at its session in Buffalo last summer. "The two bodies," he says, "differ about as much as the average go-ahead American differs from the easy-going, conservative German, who fully believes in the philosophy of rest and recreation. While in the American Association success is estimated by the number of papers presented, the main point with the Germans is to have a good time, and scientific work is of secondary importance. The constitution of the German Association is a curiosity in its simplicity, and its eighteen paragraphs hardly fill one small octavo sheet; by-laws do not exist at all." The association has existed since 1822, and has held fifty-nine annual meetings, having been prevented five times from meeting by war or epidemic. The association devotes its time largely to medical research, and of the thirty sections which compose it, nineteen are for the advancement of different branches of medicine. Though the organization is of the loosest possible, there is no doubt of its permanency; its very age shows that of itself.

The Blood-Corpuscles and the Liver.—In health, as is now well known, the effete red corpuscles are broken down in the liver, a great diminution occurring in the number of corpuscles found in the portal vein—a diminution which, during active digestion, is often as great as from 1,000,000 to 2,000,000. The effete hæmoglobin thus brought to the liver is, under ordinary circumstances, converted into pigment and urea; and, as the recent experiments of Dr. Noel Paton show, any increase of hæmolytic action results in an increased formation of urea and an increased amount of pigment in the urine.—C. H. Ralfe, in *The Lancet.*

Endemic Idiopathic Bubo.—Dr. E. Mory, surgeon to the Dutch cruiser Atjeh, in Curaçoa, describes what he thinks to be a hitherto unrecognized morbid condition, which he calls "bubo-adenitis idiopathica endemica." He saw eighteen cases, all but one occurring in European new-comers, aged from eighteen to thirty-five. The disease developed itself, always rather acutely, in the course of three or four days, and consisted in the appearance of hard, painful, and very tender swelling of the inguinal lymphatic glands on one or both sides, the size of the tumor varying from that of a hen's egg to that of a man's fist. The swelling was accompanied by general malaise, slight fever (100° to 103° Fahr.), loss of appetite, and constipation. As a rule, the patients (sailors) remained disabled for about four weeks, then the swelling decreased, and pain was felt only after prolonged standing or walking. A complete resolution, however, was not observed in any of the patients up to the date of the article (for six months). Local therapeutic measures (iodine, mercurial ointment, iodoform, collodion, blisters, Goulard's water, cataplasms, massage, injection of a two per cent. solution of carbolic acid or ergotin) remained entirely useless. General means (salicyl, quinine, regulation of the bowels, absolute rest, light laxatives) only improved the constitutional state of the patients. Dr. Mory thinks that the disease in question is caused by an infection with the microbe of elephantiasis.—*British Medical Journal.*

The New Cure for Profanity.—A correspondent who is a "country doctor" has evidently been thinking a great deal upon the vaunted merits of anacardium, one of the homœopathic remedies for profanity. He calls attention to the fact that an item giving points in the use of this remedy appeared some time ago (September 4, 1885) in The Medical Record. The author of the original article, a contributor in a homœopathic journal, stated that one of the provings of anacardium was to induce profanity, but he recommended its use only in those cases in which the habit was a symptom of mental disease and not of loose morals. Anacardium, said this writer, cured a minister of the habit. Another remedy mentioned was nitric acid—we presume in very small quantities. We thus condense our correspondent's letter, and merely give his conclusions: "Most of my patients are attacked suddenly, and the paroxysms are very severe. The disease is apt to become chronic, however, if the cause is more or less persistent. An esteemed patient of mine drifted into this form by persisting in using a stylographic pen. I did not know of the new medicine at that time, and so had no opportunity of trying its continuous effect. Although this new remedy may be efficacious in mild cases, where the causes are trivial, in the severe paroxysms I can imagine it would be of small account. In the latter the case assumes that of a pronounced mental reflex, and, for the time being, appears to be incurable. The most marked example of suddenness of attack was in a clergyman who struck the bridge of his nose plump against the edge of a door in the dark room. He was for the time being entirely unconscious of his ejaculations. I have placed him under the remedy, and with a little care in avoiding the cause he has a promise of recovering his mental equilibrium. Another example of this paroxysmal mental reflex was in the person of a mild-mannered bank clerk who stubbed his toe during a moonlight stroll on an irregular plank-walk. This man refused to take the medicine until his toe felt better, so I had no opportunity for testing its merits. While it is always best to remove and prevent the cause of profanity, it is well to treat all patients who are predisposed to the disease by a continous course of medication up to the point of saturation. If this can be done it is not impossible, perhaps, for the patient to smile complacently when left by his train, or bless his stars when he slips on a banana peel."

Urticaria from Cow's Milk.—Dr. S. S. Cartwright writes that Dr. S. W. Reed, of Margaretville, N. Y., has a little patient, seven years old, in whom the use of cow's milk always produces an eruption of urticaria. Some four or five years ago he ordered milk for her, and, though told of the idiosyncrasy, insisted that she should take it. She did so, and was soon covered with an eruption of urticaria. A few days ago he ordered a poultice of bread and milk for a swelling on the child's neck, and in less than two hours an eruption of urticaria covered the neck and entire side of the face.

Musical Discrimination in a Dog.—Dr. W. H. Walshe says that he once saw a dog who invariably uttered a heart-rending howl when the note F sharp on the fifth line of the treble clef was struck on the piano. He had seen him rouse up out of apparent sleep at the sound. The animal proved, under repeated trials, perfectly indifferent to the semitone above and below that note, to its octaves, and, in fact, to all other notes.

The Medical Record

THE VALUE OF QUININE AS AN ANTIPYRETIC IN PNEUMONIA.[1]

BY JOHN H. RIPLEY, M.D.,

VISITING PHYSICIAN TO ST. FRANCIS HOSPITAL, NEW YORK.

IN 1877, assisted by my lamented house-physician at St. Francis Hospital, the late Dr. Frank A. Langworthy, I made a number of experiments in order to test the value of quinine as a remedy in pneumonia, with especial reference to its alleged power to control the temperature. These experiments have since been added to, under my direction, by my successive house-physicians, Drs. C. M. Cauldwell, John Dorning, Frank E. Miller, M. L. Warrin, Arot Spence, and Horace B. Sweetser. This paper is based, principally, on forty-eight experiments, although a much larger number has been made; but, from various defects, the others have not been considered, though giving substantially the same results. The plan pursued was as follows: The drug was given as early as possible after the onset of the disease, and was tested in those cases only having a temperature of at least 103° F. The unmodified course of the disease was uniformly watched for several hours preceding the experiment. An effort was also made to obtain uncomplicated cases. The quinine, when administered by the mouth, was nearly always given in solution. The temperature was always taken in the rectum, the thermometer kept in the bowel three minutes for each record, and no change of thermometers allowed during any one experiment. No experiment lasted less than four hours, and a majority of them from six to twelve hours. In the earlier cases the temperature was taken every fifteen minutes; but as this proved to be a most laborious, as well as unnecessary, task, the intervals were subsequently prolonged so as to make the records half-hourly or hourly. The effects of the drug on the respiration and pulse were noted in about two-thirds of the cases, and certain other phenomena were also observed, to be referred to later on. The time of day of administration varied, but when a single dose only was given during twenty-four hours, the morning was generally selected, as it gave a longer period for observation; still, all parts of the day were represented. The patients were nearly all adult males, from nineteen to forty-five years of age. There was one child, a girl, five years of age, that took a number of large doses hypodermically. In 20 experiments a single dose of twenty grains of the sulphate in solution, by the mouth, was given; in 5, thirty grains; in 3, thirty grains daily in five-grain doses every two hours; in 2, thirty five grains in the same way; in 8, forty grains at a single dose, by the mouth; in 3, twenty grains hypodermically; in 3, fifteen grains hypodermically; in 3. ten grains hypodermically; and in 1, eight grains hypodermically. Results: In 1 case a reduction of temperature amounting to 4° took place after a dose of forty grains by the mouth, and in the child the temperature fell $3\frac{1}{2}$° five hours after a hypodermic injection of fifteen grains, this having been preceded by one of ten grains five hours before the second. There are 5 instances of a reduction of from $2\frac{1}{10}$° to $2\frac{1}{2}$°. There are 23 experiments showing a reduction of from 1° to $1\frac{4}{5}$°. There are 14 showing a reduction of less than 1°. There are 2 showing no reduction, and 2 with a slight elevation. The reduction here noted is the lowest point reached at any time during the observation. It was always of short duration, generally only a fraction of an hour.

There was no uniformity either in the time at which, after the drug was given, the temperature began to fall, or in the *duration* of the fall. In a large number of cases a slight lowering took place within fifteen minutes after giving the quinine, while in others it began in from half an hour to three hours. The time between the beginning of the fall and the commencement of the permanent rise was from two to ten hours—the longer duration was very exceptional. Neither was the statement of Jürgensen verified, that "the line of descent and subsequent elevation is very nearly straight." The temperature, even when taken every fifteen minutes, was found constantly varying, at one time a fraction of a degree lower, and then again higher, with, in a few cases, a lowering tendency.

The effect on the pulse and respiration, as to frequency, was neither consonant nor uniform; both were generally slowed, the pulse more often than the respiration—sometimes one was hurried and the other retarded. The impression made on the pulse and respiration was not a constant guide to that produced on the temperature.

Of the six instances mentioned above, in which the temperature was reduced over 2°, there was, pretty clearly, malarial poisoning in four, and in one the experiment was made on the seventh day of the disease, and the temperature never rose again after the recession, although no more quinine was given. Excluding these cases as not being fairly illustrative, the greatest reduction obtained was one and a fraction degree, except in a single instance. Practically, then, so far as we can judge from these experiments, the most that can be expected of from twenty to forty grains of quinine, administered daily to patients in the active stage of acute lobar pneumonia, is, that it will reduce the temperature between 1° and 2° F. in about half the cases, while in the other half the reduction will amount to less than 1°. When we add to this statement the fact that the lowest points reached are not even approximately held with certainty more than two to four hours, the results appear even less striking. It is not improbable, also, that in a number of instances the effect of the drug was apparent only, as such recessions of temperature occur, during the course of pneumonias, in the absence of all medical treatment.

That quinine is a feeble and uncertain antipyretic in pneumonia, is the conclusion arrived at from an analysis of the foregoing experiments. But this is not the only argument against its use. Contrasted with its inefficiency as an antifebrile are some marked deleterious effects on the digestive, circulatory, and nervous systems. When given by the stomach, even in moderate doses, if frequently repeated, it soon produces anorexia and nausea. In larger doses it not infrequently excites violent retching and vomiting, and prolonged intolerance of food and stimulants. Marked cardiac weakness, lasting several hours, and sometimes associated with dicrotic pulse, generally followed the maximum dose in these cases. Profuse, often cold, perspiration was another effect, taking place in from one to two hours after giving

[1] Read at the meeting of the New York Academy of Medicine, January 20, 1887.

the quinine. Epistaxis occurred in about twelve per cent. of the cases. Profound nervous depression, somnolence, delirium, muscular twitchings and tremblings, dilated pupils, and in two instances opisthotonos, were some of the results on the nervous system. In three cases the urine was examined both chemically and microscopically, before and after the ingestion of the larger dose of quinine. Chemically, albumen was much increased in quantity after the quinine in one case, and there also appeared in this specimen renal mucus and hyaline casts not present before.

These injurious effects of the drug more than counterbalance, in my opinion, whatever of good may be derived from its slight temporary reduction of fever. I cannot find in the history of these cases any evidence supporting the theory that it either shortens the course of the disease or lessens the mortality. Frank, uncomplicated cases have run the usual course in spite of it; while in other cases, portions of the affected lung hitherto unaffected, as also parts of the opposite sound lung, have become inflamed while the patient was under the full influence of it. I believe, also, that too much importance has, of late, been attached to the necessity of reducing temperatures, especially those of moderate degree. It is a matter of daily observation that patients with slowly resolving pneumonias, or with typhoid or typhus fever, bear such temperatures for weeks and still make good recoveries. Certainly, in the case of typhus and typhoid fevers, of which we have had, during the last few years, a very large number in the hospital, the mortality has been markedly less since we abandoned the former heroic measures for reducing temperature. Why should it be deemed necessary, then, in the case of ordinary pneumonia running a short course, to ply the patient with antipyretics?

That quinine given in pneumonia has any influence in arresting cell-migration may well be doubted. The crude experiments made on lower animals and reptiles seem to me to fall far short of a demonstration that the same effect will follow the introduction of the remedy into the system of man, by any of the ordinary methods of administration. In order to produce this inhibitory effect, Brunton says it would be necessary to give a full-grown man from forty-five to sixty grains. Of course this dose must be repeated every few hours, in order to continue our control over these little wanderers. It is unnecessary to say that this treatment could not be carried out. But leucocytes constitute only a small part of the exudates in pneumonia, and, granting that they all come by transudation, not much would be gained by their suppression. Much more would a remedy against them be indicated at a later stage in the disease, or even in a purulent bronchitis.

In conclusion, I believe that large doses of quinine should be abandoned in the treatment of pneumonia. If an antipyretic be indicated, we have in antipyrine, or even salicylate of soda, a remedy more certain, more powerful, and less injurious.

Forty-eight Experimental Cases of the Value of Quinine as an Antipyretic in Pneumonia.

No. of experiment.	Disease.	Temperature.	Amount, form, and method of giving drug.	Length of time observed.	Results on temperature.

38 to 44 inclusive a child five years old.

Cocaine in Circumcision.—Dr. Charles Milne, of this city, seems, at present accounts, to have been the first to use cocaine in this operation, antedating the cases referred to in a recent issue of The Record. The case was one of hypospadias in a child two and a half months old, the operation being for the removal of the prepuce which was on the upper surface of the penis. An injection of eight minims of a four per cent. solution of cocaine was made into the prepuce, and the mass was removed without pain. The operation was performed on December 3, 1884, and was reported by Dr. W. O. Moore in a paper read before the New York County Medical Society on December 23d of the same year.

DEFORMITIES OF THE NASAL SEPTUM.

A New Operation for their Correction, with an Analysis of its Results in One Hundred and Sixty-six Cases, as Throwing New Light on the Pathology of Diseases of the Upper Air-tract and their Relation to the so-called Nasal Reflexes.[1]

By F. H. BOSWORTH, M.D.,

NEW YORK.

During the past two years I have operated upon a large number of cases of deformity of the nasal septum, in which the results of the operation have presented so many points of interest that I have felt myself justified in bringing them before you to-night, not only as demonstrating an unusually successful method of dealing with a very large proportion of cases of ordinary catarrhal disease of the nasal passages, but, which is of far greater interest, as throwing much light on the pathology and development of so-called "nasal catarrh," and its relation to diseases of the lower air-passages.

I purposely avoid repeating the very extensive observations which have been made by various writers, and the large statistics which have been compiled showing the frequency and character of septal deformities as the result of the study of skulls. From an ethnological point of view, possibly, they possess a certain amount of interest; from a clinical point of view I cannot but think the observations are deceptive, being made on the dry skull, in which the cartilages are entirely absent, and the vomer probably warped in the process of drying. Observations on the living subject and dead-house study certainly give us results of far greater accuracy. Classifications based on this method of study have been made by numerous and careful writers, which, in general, may be described as classifications based on the direction and extent of the deflected portion, as involving the cartilage alone, or the cartilage and vomer together, and as presenting ridges horizontal or vertical in direction. These observations, as made by Chassaignac,[2] Jurasz,[3] Lowenberg,[4] Jarvis,[5] John Mackenzie,[6] Gleitzmann,[7] and others, are undoubtedly correct. My own observations, however, lead me to think that there is a large number of cases of nasal obstruction due to deformities in the septum which cannot properly be classed as deflections. I would suggest, then, as covering the ground, a classification as follows: Deflection of the cartilaginous septum alone, in which we have the cartilage bent upon itself, as it were, and presenting a more or less obtuse angle in one or the other nostril, in which the projecting ridge in the majority of cases is vertical. Second, very rarely we have a deflection confined to the cartilage in which the projecting ridge approaches to the horizontal line. Third, perhaps the most frequent of the class of cases of genuine deflection is that in which the whole of the nasal septum, including both the cartilage and the bone, is bent to one or the other side, forming a ridge in which the projecting edge runs from before backward and upward. Fourth, still more rarely we find cases in which the cartilage is bent to one side, while the vomer is deflected to the opposite side, forming, as it were, a sigmoid flexure, producing obstruction in both sides. This classification is not a novel one, and in general is the one adopted by most writers. In addition, however, to these true deflections, we find a large number of cases which present a deformity of the nasal septum which cannot be called a deflection.

This deformity consists briefly of a prominent ridge running along the sutural lines, and which may be classed under three heads, in the order of their frequency, as follows: First, that in which the ridge is found along the line of junction between the vomer and the palatal process of the superior maxillary bone; second, that in which the ridge is found extending along the junction of the cartilage of the septum, and of the vomer, and ending abruptly at the junction of the upper border of the septal cartilage and the perpendicular plate of the ethmoid; third, that in which the ridge extends along the whole anterior edge of the vomer, including its union with the cartilaginous septum as well as the perpendicular plate of the ethmoid bone. This deformity is most frequently confined to one side, but may be developed on both sides of the same suture. It consists in a sharp-pointed spur or ridge, as it were, projecting on one side of the septum, with in no case a corresponding depression on the other. It is, therefore, not a deflection in any sense of the word. I know of no better way of explaining its existence than to regard it as a chronic arthritis, or, perhaps, a deforming arthritis as the result of an injury. The ordinary deflections of the septum we can easily understand as being the immediate result of traumatism; a blow on the nose producing a fracture of the cartilage, or of the vomer, and a permanent displacement, with or without acute symptoms. When we consider the prominence of the nose, and its liability to injury from any cause, we can easily understand how a deformity or a deflection of the septum would be one of the most frequent of occurrences, and I think it is far more frequent than is generally supposed. And, furthermore, without discussing the obscure and somewhat curious causes which have been assigned by various writers for the occurrence of these conditions, it is certainly a growing conviction in my mind that they are all, both deflections and deformities, due primarily to traumatic causes. Many instances, especially of deflection of the septum attended with gross deformity externally, are easily traceable to a specific injury, such as a fall or a blow. The large majority of the cases, however, I am convinced, are due to a mild traumatism, possibly of so slight a character as to be overlooked at the time, which has set up morbid changes which have developed marked symptoms at a later stage. This I regard as certainly the most rational method of explaining the deformities which I have described. Probably in a majority of the cases the injury has occurred during childhood, or even in infancy. Few babies when first learning to creep but have occasional tumbles, striking the nose. When we consider the character of its supports, it is difficult to see how these apparently trivial blows may not result in an arthritis, or even a deflection, which at the time gives rise to no symptoms whatever, but which in later years may develop very serious and very annoying symptoms. In a certain number of cases it would seem as if the two lamellæ which make up the vomer, as the result of a direct blow on the nose, were spread apart, sliding laterally, as it were, upon the junction with the superior maxillary, one lamella in one direction and the other in the opposite, forming thus a prominent spur in either side. Occasionally we see the lower edge of the vomer as a whole driven to one side, but far more frequently the two lamellæ separate in the manner described. That this sutural separation must result in a certain amount of arthritis is easily understood—this arthritis resulting in a thickening of the joint, and thus in a structural deformity. How this injury, occurring in infancy, may result in no untoward symptoms until ten, fifteen, or twenty years later I hope to make clear to you in the analysis of the cases presently to be given.

In the treatment of deformities of the nasal septum the object in view has been to restore normal nasal respiration. One of the earliest operations resorted to for this purpose was that of Blandin,[1] who made use of an instrument not unlike an ordinary shoe-punch, by which he removed small disks of the nasal septum at the projecting portion of the deflection, thus making an artificial per-

[1] Compend. de Chirurg. Prat., tom. iii.

foration of the septum. Now, in itself a perforation of the septum does not necessarily weaken the supports of the nose, nor give rise to any unpleasant symptoms; except that in a few cases which I have met—fortunately rare—the perforation gave rise to a whistle on inspiration. Unfortunately Blandin's operation, while relieving certain cases, was not capable of relieving the majority of them, while the extent of the deflection in many cases absolutely contra-indicated the removal of all of the offending tissue.

Probably a more rational operation was that of Adams,[1] which, in short, consisted in refracturing the septum by means of a broad, flat-bladed forceps, and afterward holding the fragments in position by the use of a screw clamp, which was worn in the nose, until the parts had become solidified. The difficulty about Adams' operation was twofold. In the first place, a broken septum has become so far thickened at the point of fracture that there is not room enough in the framework in which it stands to restore it to its original plane, and, furthermore, the point of fracture is the most difficult part of all the septum to break over, and even after extensive comminution prominences would still remain sufficient to impair the success of the operation. Moreover, the operation itself, as well as the subsequent treatment, were exceedingly painful.

I have performed Adams' operation in a number of cases, and while not a failure, in no instance was the result thoroughly satisfactory.

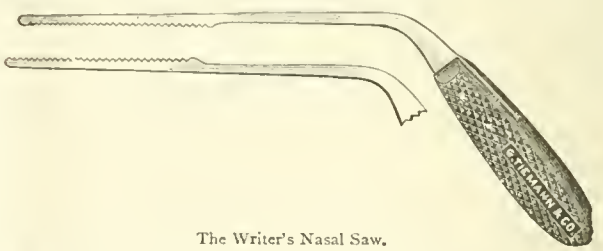
A still later operation was that suggested by Dr. A. J. Steele,[2] of St. Louis, who modified Blandin's punch in putting upon one of its blades a number of crossing knives in such a way that it would make stellate incisions through the septum, reducing the deflection part to a series of tongues or flaps, which could then be more easily brought into a vertical plane. Steele's operation was a great improvement on Adams' in that it substituted for irregular comminution definite and regular incisions. This operation again, however, is only adapted to a very limited number of cases, but is still valuable in those cases in which the deflection is confined entirely to the cartilaginous septum.

Dr. Ingalls,[3] of Chicago, has suggested a very ingenious little plastic operation on the septum, from which he reports most excellent results. His operation, in brief, consists in dissecting up the mucous membrane, cutting out a wedge-shaped piece of cartilage, and uniting the edges. Ingalls' operation first recognized the fact that there is redundancy of tissue in the deflected septum which will not admit of its being restored to the median line without first removing some of this redundancy.

Dr. Jarvis,[4] of New York, has also devised a method for operating on these cases, which consists in removing the offending tissue by means of the snare, transfixing-needle, and scissors, the details of which I need not describe. Dr. Jarvis secures most excellent results from his operation, as we can well understand from so skilful an operator. In my own hands, however, Jarvis' method has failed to secure that complete restoration of the nasal passages, necessary to a perfect result.

The rather novel and ingenious suggestion of Dr. John B. Roberts, of Philadelphia, of straightening and holding in position a deflected septum by the insertion of a pin, which is embedded within the cartilage in such a manner as to restore it to its normal plane, I have tried in a few cases. The operation is feasible only in cases of cartilaginous deflection, but in these is undoubtedly of much value.

These various operations have failed in my own hands to meet the requirements of the very large majority of my cases. Recognizing the fact that there was a redundancy of tissue in all cases, which must be gotten rid of, and that the object to be kept in view was to restore the nasal septum as nearly as possible to its original contour, I first tried paring away the projecting portion by means of a knife, as suggested by Chassaignac and Gross. I very soon, however, found that while my knife would easily go through cartilaginous tissue, it failed to make any impression upon bone, and, furthermore, that in the very large majority of cases the offending tissue was in part, or in whole, bony in character. I then resorted to several devices in the shape of cutting forceps and gouges, which I soon found were not only very painful, but exceedingly unsurgical; they failed to do the nicer work that was required. I finally concluded that the only instrument which could do the work was a saw. I procured one of Lent's subperiosteal saws, which, as you know, is a small, fine-bladed saw, mounted on a straight handle. This I found worked very well in a few cases where the projection presented at a prominent angle. In those cases, however, in which my saw was compelled to enter at a very sharp angle, the instrument failed to take hold. Furthermore, my hand obscured vision so far as to interfere with the operation. I then had a saw made with a thin blade, attached to a large handle at an angle of forty-five degrees. The saw was made with teeth set and crosscut, and on the ripsaw pattern, that is, with a forward trim to the teeth. This instrument did better work, but I still found difficulty in making it enter at a sharp angle. I then had the set removed from the teeth, still making the blade as thin as possible, and had the crosscut removed, the teeth being filed at right angles. I still met with difficulty in that the cutting had to be done with a single motion. I could not enter the saw, but could only cut with the motion of withdrawal. I finally gave the following directions to the instrument-maker: The blade to be as thin as possible, consistent with strength, an eight of an inch in width, five inches long, with a cutting edge of three inches, thirty teeth to the inch, each tooth an exact equilateral triangle, with no crosscut, and no set to the tooth; the handle being three inches long, attached at an angle of forty-five degrees. (See Figure.)



The Writer's Nasal Saw.

With this instrument I have now performed a series of operations, which I report to you to-night, with results so uniformly successful that I have felt myself justified in bringing it before you. The operation itself has been so successful that I feel convinced that it places in our hands a method of dealing with this troublesome condition which promises more uniformly good results than any other mode of procedure. But the results which I have obtained I think possess a far greater interest in that they throw a flood of light, it seems to me, not only on the pathology of intranasal disease, but also on the connection between diseases of the nose and the series of so-called nasal reflexes, such as asthma, deafness, cough, and other disorders. Before entering upon the report of my cases, I may say with regard to the operation itself that with the use of cocaine it is absolutely painless. I am disposed to think that we have been using cocaine in entirely too weak solutions. My own experience teaches me that a twenty per cent. solution is both more economical and more satisfactory in its action as an anæsthetic than the weaker solutions.

My mode of procedure has been as follows: First, with a Delano atomizer a twenty per cent. solution of cocaine is sprayed into the nostril, both on the obstructed and on the open side. At the end of two minutes a probe,

[1] British Med. Jour., October 2, 1875.

[3] Trans. Am. Laryngological Assn., 1882, p. 61.
[4] Trans. Am. Laryngological Assn., 1882, p. 69.

wrapped with cotton, is dipped into the same solution and swept over the projecting portion of the septum, the membrane being by this time so nearly anæsthetized as to tolerate a thorough probing. The cotton pellet is used to bring the cocaine in more thorough contact with the septum, and also for more thorough exploration of the extent and character of the deviation. At the end of six minutes the parts are thoroughly anæsthetized. The saw is now introduced, and fixed in such a position that, in cutting, the whole of the projecting portion will be removed, the object being kept in view always to reduce the septum as far as possible to its normal outlines. In other words, it is to be sawed down as we saw a board out of a log. After the instrument has entered, the sawing is done with as rapid a motion as it is possible to give the hand, care being taken to make a straight cut without bending the instrument. In this way the saw is carried directly down through both bone and cartilage until it emerges at the lower edge. Occasionally I have used the reverse manipulation, and sawed from below upward, where the deflection was of such a character as to interfere with entering my instrument well above the point where the projection bent from the median line.

After cutting, the piece is generally easily removed by the forceps, or, if not thoroughly cut through, it can be removed by slipping the loop of the snare over it. The bleeding is profuse for two or three minutes, but in no case have I had any serious annoyance from hemorrhage. In two instances, I think, I have been compelled to plug, but in only two. Hemorrhage is arrested by clot, and I simply direct my patient not to expel the clot for three hours, when I think all danger of hemorrhage has ceased.

In regard to the operation, in only a single case of all the operations which I have performed have I cut through the septum, which illustrates the fact of its marked thickness at the point of fracture, and, furthermore, explains why Adams' operation for straightening is so often unsuccessful. I present here the pieces removed, which, as you see, although shrunken by alcohol, still show the character of the deformity as it existed, the relief that it must necessarily have given, and the cleanliness and surgical accuracy of the operations.

Objection has been made to these operations that they result in ulceration. Now I wish to say, in as positive a manner as possible, that in no case have I had any such result. The subsequent treatment is nothing. The healing process requires no attention. The parts heal up kindly, and, as a rule, with no unpleasant symptoms during the process. It has been charged that bad cicatrices result. Again, I say that I have seen no such result in any case. The mucous membrane reforms over the cut surface, and at the end of two months it would be difficult to recognize the fact that any cutting had been done. Too much importance cannot be laid on the necessity of a perfectly straight, smooth-cut surface. In one or two instances in operating I bent my saw, which is exceedingly flexible, in such a way as to make a hollow cut, sawing in a curve, as it were, leaving a depression on the surface of the septum. Whenever I have made such a mistake there has been exceedingly great annoyance from delayed healing, owing to the fact that mucus and bloody pus accumulated in the depression and formed crusts, and thus markedly interfered with the healing process. And herein, it seems to me, lies an objection to the rougher operation of the gouge and the forceps in removing these obstructions, as leaving an irregular surface for the lodgement of mucus and secretions. This, however, does not form ulceration. We meet with no ulcerations in the nasal cavity, except as the result of syphilis or some blood-poisoning. Delayed healing may occur, but not ulceration, after the operation; and delayed healing, I am positive, can only be the result of unskilful operating.

I will only add, with regard to the operation, that it should always be done, if possible, with the use of sunlight or some equally powerful illuminator.

The symptoms of a deformity of the septum, as will be seen later, are, I take it, the symptoms of the diseases to which it gives rise, viz., catarrhal inflammation, involving a greater or less extent of the upper air-passages. There is, however, one direct symptom which I regard as pathognomonic, and that is, an alternating stenosis of the nasal passages, by which the nasal obstruction sets in first on one side, then on the other.

This symptom is due to the marked weakness of the muscular coats of the blood-vessels, which is one of the earliest results of a nasal stenosis from a deformity of the septum, the diminished atmospheric pressure beyond the point of obstruction causing a chronic congestion, as will be seen farther on.

Recurring attacks of epistaxis, often excessive in character, are a frequent symptom, due to a slight erosion developing at the apex of the projection. These are far more frequent in slight deformities than in extensive ones, as the erosion, I deem it, is due to the ingoing current of inspired air, dust-laden as it often is, acting in a small way on the principle of the sand-blast. I might add that I have rarely seen a case of recurrent epistaxis in which the source of the hemorrhage could not be traced to an erosion at the apex of a deflected septum or in the concavity of the opposite side, where the erosion is due to the lodgement of incrustations.

The diagnosis should be a very simple matter in our day, when the cavity can be so thoroughly inspected after the reduction of venous congestion by the application of cocaine.

Any irregularity or projection in the vertical plane of the septum, of sufficient prominence to interfere even slightly with the free passage of air, must, I think, be regarded as an abnormality requiring correction.

A very distinguished authority on diseases of the throat has recently stated that "the appearance of the interior of the nose varies immensely in healthy persons." If by this is meant that the normal nasal cavity varies in appearance, I certainly take issue with the statement. A normal nasal cavity presents, in brief, a septum in the median line and in a vertical plane, each side of which presents a flat, smooth surface. This is flanked on either side by the turbinated bones, covered by a mucous membrane, in which a morbid condition should be recognized by the same tests by which we recognize morbid conditions of a mucous membrane in any other part of the body. Any departure from these conditions constitutes a morbid condition.

I have frequently heard the remark made by specialists that they have never seen a healthy nasal cavity. This seems to me a most lamentable confession. Healthy nasal passages are very common, and I have frequently had patients referred to me for examination whom I have sent away with the assurance that there was nothing for me to do. These were, of course, patients sent with reference to some supposed reflex disturbance.

During the past two years I have performed this operation on one hundred and sixty-six patients of whom I have kept records. This does not include a large number of cases operated upon casually, of which I have kept no records, and cases at my clinic at Bellevue, of which the records were imperfect. It includes only those cases which have been operated upon in my private practice, wherein the records were sufficiently accurate to warrant my making absolute statements in regard to them. These cases include all of those which have been recorded, without selection.

Its Relation to Hypertrophic Rhinitis.—Forty-five cases operated upon were for ordinary so-called naso-pharyngeal catarrh. I have never yet learned what was meant definitely by the term naso-pharyngeal catarrh. As far as I know, it had never been accurately located until the second volume of Mackenzie's work appeared, wherein it is described as catarrhal inflamma-

tion of the naso-pharynx, or vault of the pharynx. I seek in vain, however, in Mackenzie's chapter for light on the pathology of the disease—a foot-note under this heading refers to the article in his first volume on "Hypertrophic Granular Pharyngitis." On referring to this, however, I find nothing on the subject. This can only be explained by the fact that there are no pathological changes here to be described; the source of the trouble is in the nasal chamber.

Beverley Robinson is more frank, for while he has given us, in the second edition of his work on "Nasal Catarrh," undoubtedly the best *résumé* of the subject which has yet appeared, he plainly acknowledges his inability to offer any suggestion as to the pathology of this affection.

I think the general impression is, however, that it is a catarrhal inflammation involving the nasal cavity and the pharynx. My 45 cases, however, gave rise to a definite train of symptoms, much as follows: There was interference with normal nasal respiration, accumulation of mucus in the fauces, hawking and spitting, aggravated on waking in the morning, and special liability to colds in the head; in fact, the ordinary train of symptoms which we meet with in so-called nasal catarrh. The operation in these 45 cases resulted in cure in 32 cases and in relief in 13. In every case the operation was fully warranted, and in the least successful case I think I may say that the relief was very great. In a number of these cases there was, in addition to the operation, a considerable amount of treatment required, consisting mainly of cauterization of hypertrophied tissue on the turbinated bones; but in a majority there was a progressive improvement following the operation, by which, at the end of two or three months, the success of the operation was more noticeable than immediately after.

Now, it seems to me there is considerable to be learned from these cases. I believe that in everyone of them the primary source of the whole difficulty lay in the deflected septum producing nasal stenosis and subsequent hypertrophic changes in the nasal mucous membrane, these constituting all the pathological changes which the nasal mucous membrane had undergone.

Its method of development is simply as follows: During infancy or childhood an injury to the nose had resulted in deflection or deformity of the septum, interfering with normal nasal respiration. With each act of inspiration that portion of the nasal mucous membrane which lay immediately behind the point of obstruction became subjected to diminished atmospheric pressure. This diminished pressure, acting on the soft, spongy, vascular tissues covering the turbinated bones, resulted in a tendency to abnormal turgescence. This action, very slight in the first few years after the injury, gradually developed a permanent hyperæmia of the blood-vessels. Now, it is a noticeable fact that if the obstruction be comparatively slight, this turgescence is developed in the narrow passage. If, on the other hand, the deflection is extreme, all the inspired air is compelled to pass through the opposite side, and this is the case in most instances, so that we have this chronic hyperæmia developing in the healthy side. Diminution of atmospheric pressure thus acts on both cavities. The result of hyperæmia, of course, is increased nutrition, and we have finally set up certain structural changes in the membrane proper. The blood-vessels, the large venous sinuses of the membrane become dilated, and the intravenous tissue becomes thickened, and we have as a result true hypertrophy taking place, a permanent structural thickening of the membrane. Now, as we have seen, the first symptom that occurs is nasal stenosis, with resultant mouth-breathing. Mouth-breathing is often said to be a habit. Mouth-breathing is never a habit; it is a necessity, due to the fact that the individual cannot get air enough through the nose. Now, this nasal stenosis may exist at the onset of the injury; but, as I have said before, the real catarrhal symptoms often do not set in until ten, fifteen, or twenty years later. The inference, it seems to me, is that this so-called vicious habit of mouth-breathing is by no means the vicious habit that has been claimed. It is not mouth-breathing which does the mischief. It is simply an adventitious feature of the disease. Mouth-breathing is not necessarily a mischievous habit. It is a necessity, and an evidence of a morbid condition elsewhere, and it is this morbid condition which causes mouth-breathing and all the unpleasant symptoms which are attributed to it.

The prominent symptom of a so-called "nasal catarrh" is the tendency to mucous accumulation in the fauces, with what is usually termed pharyngitis. Now, it is a popular impression that the excessive secretion of so-called faucial catarrh is due to the pharyngitis. But I have examined the pharynges of a vast number of patients, and I am convinced that pharyngitis is one of the rarest of throat diseases. The pharynx belongs to the food-tract, and not to the air-tract. The pharynx is inflamed oftentimes in connection with chronic gastritis, but never, I think, or very rarely, in connection with inflammation of the air-passages. The excessive secretion of so-called pharyngeal catarrh is not from the pharynx; it is from the nasal chambers; from the hypertrophied mucous membrane largely. It is a very popular impression that this so-called nasal catarrh gives rise to an excess of secretion; that a mucous membrane, the seat of chronic inflammation, pours out an increased amount of mucus. I think this is exceedingly doubtful. I believe the real truth of the matter is that, instead of increased secretion, there is probably diminished secretion. Certainly there is no marked increase of the secretion, as is the popular view. The secretion is perverted to that extent that it becomes thick and inspissated to a degree that it is not removed by the ordinary efforts at expectoration. The normal secretion of the nose is a very thin fluid mucus, of about the consistency of a thin syrup, so rendered by the exosmosis of serum from the turbinated tissues, which probably in the twenty-four hours amounts from fourteen to sixteen ounces. The nasal mucous membrane pouring out this large amount of serum, the mucus becomes diluted to that degree that it can flow freely into the fauces and, even, in large amount, without the patient being conscious of it. Now if the turbinated mucous membrane is thickened and hypertophied, as the result of a long-standing hyperæmia, the natural consequence is that the exosmosis of serum is interfered with, the normal nasal secretion becomes thick, and is removed with exceeding difficulty. Moreover, in the place of the normal transparent mucus we have a muco-purulent discharge, as it were; a discharge which contains a large number of epithelial cells, the excessive proliferation of epithelium being a part of the chronic hypertrophic process. In the forty-five cases already alluded to the success of treatment was primarily due to removal of the primary cause of the disease—as I take it, the obstructing deflection of the septum. After removal of that we were ready for the successful treatment of the hypertrophied membrane which had resulted from the deformed septum. The destruction of the hypertrophied tissue and the removal of the septum completed a perfect cure in these cases.

I think it but just to myself to say that in the thirteen cases which I report as only relieved, and not cured, some of them were so far benefited as to cease treatment. In others the deformity of the septum presented conditions which were beyond my manipulative skill to remedy, for I might say here that whereas a very large majority of the cases of deformities of the nasal septum are amenable to the operation which I have reported, we occasionally certainly must meet with cases which are beyond the reach of our skill, the deformity being so located high up in the nasal chamber, or so far back, as to interfere with the success of the operation. The teaching, however, remains, and it seems to me is unmistakable. The removal of an obstructing piece of the cartilage, which in itself performs no important physiological function, cures a long-standing catarrhal disorder. Its action is to re-

store normal atmospheric pressure to the membrane, thereby diminishing turgescence and restoring normal blood-supply, and, consequently, normal nutrition, to the part.

I have stated that the faucial secretion in nasal catarrh was due to secretion from the nose passing into the pharynx; this is only partly true. Much of the secretion in the fauces has its source in the glandular tissue in the pharyngeal vault. This mass of glands pours out a very large amount of clear, transparent mucus, whose function is to lubricate the bolus of food, and to facilitate its passage into the stomach. In health this secretion passes down behind the palate in large quantities, and without one being conscious of it, as all of us have noticed many times in examining the lower pharynx. Now, in hypertrophic rhinitis, as I have already asserted, the membrane is so much thickened that exosmosis is seriously interfered with. Hence the inspired air reaching the upper pharynx has a tendency to dry and render inspissate the mucous secretion there found; it lodges, therefore, a thick tenacious plug, which is voided with much difficulty. We have here again markedly diminished secretion, giving rise to a so-called naso-pharyngeal catarrh, and not an excessive secretion. That this is the true view, I think, is the unmistakable teaching of these operations. It has been the fashion in past years to treat naso-pharyngeal catarrh by local application to the pharyngeal vault, and we have a number of instruments, named after their devisers, to facilitate this manipulation. I doubt if a single case of the disease has ever been cured by this method. If it can be cured by operation on a deformed septum, without further measures, there can be but one conclusion—my reasoning is correct.

Its Relation to Chronic Rhinitis.—Twenty-one operations were done for simple chronic rhinitis, in which there was marked turgescence of the mucous membrane without structural hypertrophy. In these cases the prominent symptoms were especial liability to cold, nasal stenosis, snuffling, and watery discharges from the nose. It was a notable fact in these cases that a majority of them were under twenty years of age. The hyperæmia had existed for longer or shorter periods, but in no case sufficiently long to give rise to hypertrophy.

The prominent condition in these cases consisted simply in obstruction of one nasal passage, due to the deflection of the septum, with hyperæmia on one or both sides; the existence of hyperæmia, in contradistinction from true hypertrophy, being in every case easily recognized, as you know, by the local use of cocaine, which, expelling the blood completely from the membrane, enables us to detect a swelling due in one case to the mere hyperæmia, in another case to hyperæmia with hypertrophy. In most of these cases the immediate result of the operation was relief without further treatment, opening up the nasal passage, admitting of normal atmospheric pressure to the whole mucous membrane, under the action of which the hyperæmia and swelling subsided. In a few cases, where the normal tension of the coats of the blood-vessels had been so far weakened by the long-continued hyperæmia, a moderate amount of treatment was required. This consisted in the application of chromic acid, a caustic which I prefer above all others. The action of chromic acid is valuable to us, not only in destroying hypertrophied tissue, but also in reducing hyperæmia; for, as you know, after the turgescence has been reduced by the application of cocaine, a few crystals of chromic acid laid upon the parts destroy the superficial layer of the membrane, converting it into a more or less dense slough which adheres closely to the surface for three or four days and holds it down, as it were, and prevents a return of the turgescence, its action being not unlike that of a film of collodion.

Let me add in this connection, that an especial liability to colds in the head is one of the prominent symptoms of the class of cases mentioned in the above head, viz., deformed septum, with chronic hyperæmia of the turbinated tissues. It is an old teaching that chronic inflammation results from a series of colds; that chronic nasal catarrh is caused by frequent colds in the head, or by neglected colds. I have taught the same doctrine within very few years. Now, there is no such disease as nasal catarrh. No one has ever yet described the definite pathological changes which characterize it, or even its locality. It is merely a symptom and not a disease. Translate it into English, and call it a nasal discharge, and we get at its proper meaning.

The liability to colds in the head is to be regarded as one of the prominent symptoms of the early stage of a chronic rhinitis, the chronic inflammation commences first. This, it seems to me, is shown conclusively in studying the development of these catarrhal troubles in the upper air-passages. The same is true of the larynx, trachea, and bronchial tubes. A mild chronic inflammation is the first morbid change, and recurrent attacks of acute inflammation become a prominent symptom.

Its Relation to Diseases of the Larynx and Bronchi.—We come now to the consideration of those morbid conditions of the larynx, trachea, and bronchial tubes which are found dependent upon the nasal disorder, and which have been more or less successfully affected by the operation. Of bronchitis and laryngitis, or simple laryngitis, with an impairment of the singing or speaking voice, there were 5 cases, 3 of which were entirely cured, 2 markedly relieved. These were cases of clergymen and professional singers. Of bronchitis there were 18 cases, 8 of which were cured and 10 relieved; of simple irritative cough, due to mild hyperæmia of the larynx, with no evidence of bronchial trouble and no expectoration, 5 cases were operated upon with perfect success; of hay-fever there were 13 cases and 5 cures; hay-fever and asthma, 11 cases and 5 cures; of asthma alone, 12 cases and 6 cures; of rose-cold, 2 cases, both cured; of rose-cold and asthma, 2 cases, both cured.

There is much in this last series of operations which is exceedingly instructive with reference to the connection between diseased conditions of the nose and diseased conditions of the bronchial tubes. In order, however, to make clear my idea, and to make my paper complete, it will be necessary to briefly allude to certain views in regard to hay-fever and asthma, already expressed in a paper on this subject read before the American Climatological Association, May 28, 1885. We are too apt to regard the nose as the organ of olfaction, whereas it seems to me this function is somewhat adventitious. The olfactory nerve probably could find no more convenient place for its distribution than in the nasal chamber, because here odoriferous particles will most readily reach its terminal filaments. But this function is quite secondary in importance to the great respiratory function of the nasal chamber. Impairment of olfaction is not a grave matter. Impairment of the respiratory function of the nose may lead to most serious results. We are told that the function of the nose is to warm and moisten and purify the inspired current of air. This respiratory function essentially consists in the profuse exosmosis of watery serum, already alluded to, by which the ingoing current becomes more or less completely saturated with water, the warming and rarifying of the air being of far less importance than this. If by any cause the mucous membrane of the nose becomes the seat of morbid changes, this function is interfered with, and one of its direct results is, I believe, the development of a catarrhal inflammation of the larynx, trachea, and frequently of the bronchial tubes, due to the fact that the air entering the passages below has not been so thoroughly fitted to enter these delicate parts that it may not do injury. The long-continued action of this process is to develop morbid changes here. We often regard a laryngitis and bronchitis as the extension of a catarrhal process from

the nasal membrane. That such is the case I do not believe. There is no continuity of tissue. As before stated, the pharynx is not a part of the air-passage, its membrane is not inflamed in connection with disease of the air-passages. Extension of the catarrhal process must necessarily involve a continuity of tissue in close physiological relation, and this does not exist. That this is the true view I think is well shown by the fact of our utter failure for many years to treat successfully catarrhal disease in the larynx and trachea by local application, and by our final and striking success in curing such diseases by removing diseased conditions in the nose, to the exclusion of any local measures whatever, directed to the passages below. That there is a close physiological connection between the nose and the bronchial tubes is shown by numerous experiments. Hyperæmia of the nose is very apt to be followed by hyperæmia of the tissues below. An irritable condition of the nose is followed by a similar condition of the bronchial tubes. The probe passed into the nose will often cause quick, expulsive cough. In my paper, already alluded to, I took the ground that hyperæmia of the nasal mucous membrane, with weakness of vaso-motor control, was the result of diminished atmospheric pressure, caused by nasal stenosis, this being the primary factor in the development of hay-fever and asthma. It seems to me that there is an additional element to be counted upon here, and that is the close, quick, and intimate sympathy between the membranes in the two regions. What this is I do not attempt to explain.

We speak of it as reflex. Are we not in danger of extending the use of this term too far? I am disposed to think that we often use it to cover our ignorance of the real connection between obscure symptoms and the real seat of disease. Whatever the relation may be, I think the inference may be clearly drawn that a morbid condition in one region is especially liable to be followed by a similar condition in the other. Vaso-motor paresis of the blood-vessels of the nose, constituting inflammation, is liable to be followed by vaso-motor paresis in the larynx, trachea, and bronchi. Complete vaso-motor paralysis in the nose, constituting hay-fever, rose cold, etc., is especially liable to be followed by complete vaso-motor paralysis of the blood-vessels of the bronchi, constituting asthma. An application of cocaine to the nose I have seen relieve an attack of asthma in less than three minutes, and this in many instances. Can we explain this in any other way than as above? A single application of chromic acid to the turbinated tissues of the nose I have seen in very many instances relieve a cough instantly. This I have done with especial success in children, even as young as two years of age.

The action of the acid was here to reduce hyperæmia in the nose, which was immediately followed by the disappearance of the tracheal and bronchial congestion. We attribute the successful use of caustics in the nose to the destruction of tissues. This I regard as a mistake. The more important action is, I think, in controlling hyperæmia. In the same manner the removal of a septal deformity is followed by relief to the overcharged blood-vessels in the bronchi.

To make my point clear, I relate the following case: Mr. G——, aged twenty-seven, consulted me early in October, with the history of asthma commencing in 1873, mild in character for three years, but for the last ten years of so great severity as to compel him to seek relief in most of the health-resorts in this country and in Europe, but without success. His attacks usually came on at night, were worse in winter than in summer, and lasted weeks, and even months. His seasons of immunity, were most frequent in warm weather, rarely lasting over a few weeks at a time; occasionally, however, three months. His family history was clear of any neurotic tendencies, and an examination failed to reveal anything other than a prominent deflection of the nasal septum to the right, and very marked hyperæmia of the turbinated tissues of the left side. I advised an operation, which was consented to, and from the day of the operation to the present he has been entirely free from asthma. His health, which before was exceedingly delicate, has markedly improved. He has gained in flesh, and his chest measurement has increased about three inches, as he tells me.

This, as an illustrative case, it seems to me, is rather striking. The operation secured two results. It opened the left nasal passage by the removal of obstructing bony and cartilaginous tissue, allowed the air to enter freely, and subjected the mucous membrane of the turbinated bones to normal atmospheric pressure, under which their turgescence immediately subsided without further treatment. I have seen this patient several times since the operation, and made applications of chromic acid to secure greater patency of the air-passages as a protective measure. But the obstruction caused by the swollen turbinated tissues on the side opposite to the deflection was due to hyperæmia rather than to hypertrophy. A further result secured by the operation, then, in addition to removing the cartilaginous obstruction, was the relief of hyperæmia of the nasal membrane, followed immediately by subsidence of the hyperæmia of the bronchial mucous membrane. Asthma, as I have stated before, I believe to be the same disease as hay-fever. In hay-fever we have a complete paralysis of vaso-motor control of the blood-vessels which supply the mucous membrane of the nose, this complete paralysis resulting in their dilatation to the utmost extent, and at the same time resulting in the paralysis of the osmotic control, the watery discharge in hay-fever being the same discharge which occurs daily in health as constituting the respiratory function of this membrane. In health, under proper control, from twelve to fourteen ounces of watery serum are poured out daily. With the complete paralysis which occurs in hay-fever the amount may be five or six times this quantity.

Now in asthma the same thing occurs practically. An attack of bronchial asthma consists, I think, in the complete paralysis of vaso-motor control of the blood vessels which supply the bronchial mucous membrane. But here we have to do with a totally different anatomical condition. The immensely rich plexus of blood-vessels in the nose, when swollen to their utmost limit, completely block up this large passage, and pour out serum in large quantities. The minute blood-vessels of the bronchial tubes, when distended to their utmost limit under this complete vaso-motor paralysis, markedly diminish the calibre of the bronchi, and so interfere with respiration. The bronchial tubes do not possess the especial physiological function of serous exosmosis; therefore they do not pour out this large quantity of serum. The prominent symptom is merely that of obstructing the entrance of air to the air-cells. In the latter stage of asthma the attack passes off with cough and expectoration. The blood-vessels relieve themselves at this stage of the attack by a moderate amount of exosmosis, the turgescence subsides, and the sufferings of the patient are at an end for a time. Furthermore, in this connection, I might say that I think we have good reason for abandoning the old classification of bronchial, cardiac, and gastric asthma. In bronchial asthma, so called, or chronic bronchitis, the neurotic element is not prominent. The chronic inflammation of the bronchial tubes is the prominent factor; the asthma is an intercurrent symptom. The so-called gastric and cardiac varieties of asthma, I think, we must consider, in the majority of cases, if not in all cases, as nasal reflexes due to a diseased condition of the nasal cavity of an obstructive character. While the exacerbations may be precipitated by a temporary attack of gastric disorder or cardiac disturbance, which we can easily understand might be produced where the vaso-motor weakness already existed in the bronchial mucous membrane, I have seen no case of asthma—and my clinical records

cover a very large number in addition to those here reported—in which the source of the trouble could not be traced to disease of the nasal cavities. It is a very striking fact, however, that in a number of these cases, in which my diagnosis proved to be correct by the result of the treatment of the nose, one of the most prominent symptoms complained of was an exacerbation of the attack as a result of indigestion, with flatulence, and I have often found difficulty in convincing my patient that the primary seat of the disease was not in the stomach.

Another symptom which might be alluded to is the exceeding great frequency with which an attack of asthma commences with a sense of irritation of the nose and sneezing.

The special points, then, which I desire to emphasize are:

First.—That a nasal stenosis due to obstructive lesion must necessarily be followed, sooner or later, by hyperæmia of the membrane beyond the point of obstruction; this occurring first in the nose, and secondly in the larynx, trachea, and bronchial tubes.

Second.—A hyperæmia in the nose is liable to be followed by hyperæmia of the air-passages beyond, as the result of an intimate physiological connection between the two, both deriving their vaso-motor control probably from the same central ganglia; this hyperæmia, either in one location or in the other, tending toward the development, first, of catarrhal inflammation with hypertrophy, as shown in the cases of laryngitis and bronchitis dependent upon nasal disease, and only relieved by treatment of the nose, and, second, in those cases in which complete vaso-motor paralysis develops in the nose, giving rise to hay-fever, which sooner or later is followed by vaso-motor paralysis in the bronchial mucous membrane, causing true asthma.

Its Relation to Ear Diseases.—Twenty-four of my cases suffered more or less well-marked impairment of hearing, the hearing distance varying from one-fortieth to one-half normal. In addition to deafness there were hyperæmia and hypertrophic rhinitis in varying stages of development. As an immediate result of the operation in all cases there was improvement in the hearing distance; and as the result of further treatment, specially indicated in certain cases, 10 cases were ultimately cured, while 14 cases were relieved. Of these 24 cases, 8 suffered from noises in the ear, 4 of which were cured, and in 4 the operation failed to afford relief.

As regards the relationship between nasal disorders and ear troubles, I, of course, cannot speak as an expert. Many striking clinical facts, however, have come within my observation, which, it seems to me, throw much light on this question. Not only in deformities of the septum, but in a large number of cases of nasal difficulty, trouble with the hearing has been present; and the frequency with which it has been relieved by nasal treatment induces me to think that so-called catarrhal deafness is not due to an extension of the catarrhal process to the Eustachian tube. In examining the orifice of the Eustachian tube evidence of catarrhal inflammation is rarely seen. The inspection simply reveals this orifice lined with a membrane perfectly normal in appearance. With my imperfect knowledge of ear pathology I think the suggestion may safely be hazarded that in a very large proportion of cases the deafness is due, not to a catarrhal extension, but to rarefaction of air in the middle ear as the result of the nasal stenosis, and the closure of the Eustachian tube from hyperæmia rather than from inflammatory action, with the resultant depression of the tympanum and its loss of elasticity.

The further development into chronic catarrh of the middle ear follows in the same manner as in the air-passages. That it arises from an extension of the catarrhal process from the vault of the pharynx I do not believe. Disease in this region is exceedingly rare, except in children; but among them the large glandular tumors, so often seen in this region, are unquestionably a most prolific source of ear disease.

As regards tinnitus I have no suggestion to make. I simply offer the clinical fact that out of 8 cases 4 have been cured by the operation. Perhaps when the otologists shall have harmonized their views regarding the pathology of this distressing affection, the mechanical action of nasal stenosis in producing it may become more clearly understood.

In addition to the above class of cases I have operated on 2 cases of chorea, both of which were cured, with a moderate amount of subsequent treatment of hypertrophic tissue; 1 case of spasm of the glottis, cured; 3 cases of vertigo, cured; 1 case of epilepsy, operated upon December 1st, since which time there has been no attack as far as I have heard.

Upon the special relation existing between nasal disorders and these nervous affections I have no disposition to speculate. Spasm of the glottis, I believe, in far more cases than we recognize, is dependent upon laryngeal hyperæmia secondary to nasal disorder. The patients with purely nervous affections were benefited in their general health by the operation. The free entrance of air to the lungs through healthy air-passages I believe to be one of the best of tonics, as I have verified in numberless cases in which I have seen vigor re-established by treatment of the nasal passages. That this is the special indication in all of these cases of nervous disorders I am not disposed to say. That the treatment resulted in so much benefit in the above cases has been a source of satisfaction.

In closing this paper I have only to say that I have endeavored to give the result of the operation with as much accuracy as my records afford. When I say that an ordinary faucial catarrh has been cured, I mean that all the symptoms which rendered it a source of annoyance to the patient have been removed. What a complete cure is in catarrh is a nice question. It consists simply in the very accurate adjustment of the relations between mucous secretion and the respiratory exosmosis from the turbinated vessels. In the cases which I have reported as cured, I think the use of the term has been justifiable. In all cases, without exception, I think I may say that the operation has resulted in relief, and in most of the cases in marked relief to my patients. Many of the failures have been due to the fact that the deformity presented features which rendered it impossible to restore the septum to its normal plane.

In presenting these cases I desire to do so in all modesty, and would simply say that if I seem to write with undue enthusiasm it must be excused on the ground of many years of futile endeavor to devise some means of curing these heretofore intractable cases. If a device presents itself by which we do cure them, and cure them in flattering proportions, I think, perhaps, some little enthusiasm may be excusable.

It should be added that this action of diminished air-pressure, as the result of nasal stenosis, has been already alluded to by Dr. A. H. Smith, of this city, in The Medical Record for August 6, 1881. Dr. Smith takes the ground that its action is to produce hyperæmia, and, therefore, hypersecretion. As will have been noticed, I am disposed to think that diminished secretion is one of the essential conditions of so-called nasal catarrh, rather than hypersecretion. I will also add that since making use of this little saw I have been shown, by my friend Dr. Butlin, of this city, who has made a special study of the diseases of the eye and ear, an arrangement of the ordinary jeweller's saw which he has been using, since 1883, for the removal of these obstructions, with great success. I can only compliment Dr. Butlin in giving him this priority, and for the readiness with which he recognized the indications for treatment and the successful manner in which he carried it out. Dr. Butlin's operations were done for the relief of ear disease.

As regards my own instrument, I claim no especial pri-

ority—a nasal saw is not especially new, others have used it. I do claim, however, to have made an instrument which may be depended upon to do the work required, and, furthermore, to have demonstrated its value.

Before I close I desire to add a few words in regard to the causes of catarrhal diseases. We hear much of our American climate as a cause of catarrh, some charging that our frequent changes are the source of the mischief, while others attribute it to the dust-laden atmosphere. Climate has much to do in aggravating an existing morbid condition in the upper air-passages, but very little to do in causing it primarily. My own conviction is, that certainly a very large majority of cases are due to the injuries above described. Atmospheric conditions and climatic changes are not harmful to healthy mucous membranes; we must, therefore, look elsewhere for the true source of these affections. That it is in these deformities, in a large proportion of cases, my observations convince me more strongly day by day. As I have shown, the injury which causes them occurs usually in childhood when the parts are soft and especially liable to injury. This, then, it seems to me, is the time when the disease is to be prevented. We attach too little importance to a fall or blow on the nose in young children; we should, I think, recognize in it, a possible if not probable source of grave trouble in later years.

26 West Forty-sixth Street.

THE DANGERS OF THE ADMINISTRATION OF ETHER IN NEPHRITIS AND IN BRIGHT'S DISEASE.

By HENRY B. MILLARD, M.D., A.M., Etc.,

NEW YORK.

The dangers thus arising are at present fortunately very well known, and I do not think that any experienced practitioner would now be likely to permit the use of ether in a case in which the existence of nephritis was recognized. There exists, nevertheless, a large number of cases of light or mild albuminuria, perhaps intermittent, and without renal symptoms or marked impairment of the health, in which the nephritis has not attained the fully developed dignity, as it were, of Bright's disease, and where the needed caution in the use of ether is liable to be, and often is, disregarded. The following case, which came most near to a fatal termination, will illustrate this:

In May, 1885, my patient, Mrs. X——, aged thirty-five, the kidneys being perfectly normal, underwent the operation of curetting the uterus, by Dr. W. Gill Wylie, some hemorrhoidal trouble receiving attention at the same time. Ether was freely administered, the patient being under its influence nearly thirty minutes. She bore it perfectly well, and no untoward results followed. In March, 1886, the patient having been exposed to severe cold, the kidneys became affected, there being evidences of slight catarrhal nephritis. Repeated examinations, however, showed no casts, and but very few renal epithelia, and though the specific gravity was low the amount of albumin was at all times slight.

I first detected albumin, March 5th, there being one-tenth of one per cent.; April 16th, specific gravity 1.003, with one two-hundredth of one per cent. of albumin; April 21st, specific gravity 1.006, one-fortieth of one per cent. of albumin; May 14th, specific gravity 1.003, one-seventy-fifth of one per cent. of albumin. Too little importance, as events showed, was attached to the low specific gravity, owing to the fact that the patient was of a very nervous temperament, and usually passed large quantities of urine. For several months preceding the operation there had been menorrhagia (it may be mentioned that the patient had uterine fibroids), and Dr. Wylie thought best to curette the uterus, which he accordingly did at 4 P.M., May 26, 1886. Ether was administered; the patient was not under its influence more than fifteen minutes; she bore it quite well, and, although she had considerable vomiting in the night, slept fairly, though she took little or no food.

The next day at 1 P.M. I was summoned in haste, and found her in a state of collapse; she was barely conscious, and could speak with difficulty, the action of the heart was very feeble and intermitting, there was great dyspnœa, and the breath had a strong odor of ether. Dr. Wylie soon after arrived, and we could not account for the collapse except in the supposition that the kidneys were at fault. Fortunately the urine passed since the operation, about eight ounces, had been kept, and we found this to be highly albuminous. A hypodermic injection of half a grain of morphine was administered, also ten drops of digitalis, and after that five drops in alternation from time to time with small doses of corrosive sublimate; whiskey was also given in small doses. The next morning she was out of immediate danger; the odor of ether was, however, apparent for two or three days. The evening of the collapse I was able to make a microscopic examination of the urine. I found acute hemorrhagic nephritis; there were hyalin, granular, and blood casts in abundance. On the 28th nine ounces of water were passed; after that the quantity increased and became abundant, amounting, indeed, in time to polyuria. The renal condition was so grave that it was followed by albuminous retinitis and dangerous cerebral congestion—June 27th, a month after the operation, uræmic convulsions being imminent. Acute catarrhal had been superadded to the original mild, chronic catarrhal nephritis. July 9th Dr. Hermann Knapp made an examination of the eyes and pronounced them to be in the convalescent stage of albuminous retinitis. At no time was there any œdema or, excepting immediately after the operation, nausea.

The patient has since quite recovered from the nephritis, by prolonged rest (nearly three months in bed), sweating, milk diet, and the use of appropriate remedies. For the three months preceding January 15, 1887, there have been neither casts, renal epithelia, nor even traces of albumin, while the average daily excretion of solids has been about seventy-five grammes. During the month of June it did not exceed twelve grammes, though she was taking then, however, next to no nourishment.

As regards the responsibility of the administration of ether in this case, there was, perhaps, too much of a division of labor between Dr. Wylie and myself, and a complication of peculiar conditions and various severe symptoms caused the real condition of the kidneys to be overlooked or undervalued. A year before, severe and dangerous vomiting was produced, by gastric catarrh in part and in part by uterine fibroids, so that the patient brought near to the verge of starvation, and nutrient enemata had to be resorted to. The urine was then carefully watched, and nothing abnormal being found, ether was freely given, and the curetting did much toward the relief of the vomiting. In the spring of 1886, as I have stated, I found only traces of albumin, and neither casts nor renal epithelia. The specific gravity was indeed very low, but, as I have said, I did not attach great importance to this, as polyuria was common with the patient, and as much of her deranged health had been attributed to hysteria by physicians, among others Debove and Charcot, who saw her with me in the autumn of 1885, these eminent practitioners being, however, wrong in this case.

Dr. Wylie had the urine of May 15th examined, and two hyalin casts with a trace of albumin were reported. In numerous examinations I had found mucous, but no inflammatory, casts, and believed these casts to be simply mucous. I placed the whole matter of the operation, administration of ether, and all, in Dr. Wylie's hands, as I had done the previous year, and I supposed he took it for granted that had I seen any objection to the use of ether I would have informed him. The urine should have

been examined by me the day of, or the one preceding, the operation. At the same time, had I found the urine no worse than May 14th, I would not then have objected to the careful administration of the small amount of ether that was required for the operation. Nevertheless, I shall never again sanction its use when there is any diffuse nephritis, before at least ascertaining that the kidneys are excreting something like the proper amount of solids; if they cannot perform fairly well the work of elimination of solids, it is safe to take it for granted that they are incapable of excreting ether from the system.

Thorny, however, as was the road that led to the eventual cure of the chronic interstitial nephritis, I am certain that nothing less than an acute illness with absolute physical helplessness on the part of the patient, who would not otherwise have submitted to treatment with any degree of thoroughness, and who was extremely imprudent in all such important matters as diet, dress, exposure to weather, over-exertion, etc., would have enabled me to bring about a healthful condition of the kidneys; and had not the progress of the chronic nephritis been arrested in the violent manner that it was, I am confident that by this time a bad condition of cirrhosis would have been established. The knowledge of whether a condition of acute or subacute nephritis preceded the use of the ether, or was produced by it, would, of course, be valuable. The patient's digestion had been greatly impaired, and there was violent vomiting, as there had been a year before, when no albuminuria existed; nevertheless it appears to me now that some of the nausea may this time have been produced by trouble of the kidneys

It is reasonable to conclude that the administration of ether must always affect the kidneys, functionally or otherwise. From the manner in which the brain, and spinal cord, and sympathetic nerve are affected by ether, it can be easily seen that the renal nerves, which are derived from the sympathetic through the solar plexus, the semilunar ganglion, and the lesser splanchnic nerve, may be so affected as to derange at once the normal circulatory conditions of the kidney, or suspend the vital action of formation on the part of the renal epithelia, or the functions of the glomerulus, producing anoxæmia or a deoxygenated state of the blood of the latter. The conclusions of Charcot (Leçons sur les Conditions pathogéniques de l'Albuminurie), deduced from the experiments of Nussbaum, Overbeck, Heidenhain, Goll, Stockvis, and others, are that the glomerulus is the seat of albuminous secretion or exudation, and that this secretion results from diminished slowness and pressure, or entire suspension of the blood-current in the glomerulus, anoxæmia resulting; increased pressure producing not albuminuria, but polyuria. The intimate and rich supply of every part of the parenchymatous and circulatory system of the kidneys is ably shown in a paper, by Dr. Holbrook, on "The Termination of the Nerves of the Kidney," read before the American Society of Microscopists, in 1883, an abstract of which I have given in the second edition of my work on Bright's disease. According to this, the nerves supplying the kidneys are mainly of the non-medullated variety, sometimes surrounding the arteries in bewildering number, encircling them around, above, and below, freely branching, bifurcating, and supplying all the neighboring formations with a large number of delicate fibrillæ, a plexus encircling every tubule; supplying the connective tissue extending into the layer known as the membrana propria, and even piercing this membrane, and penetrating into the epithelia and the cement substance between them; the nerve-fibres also give off delicate ramules to the afferent vessels, by which they enter the tuft and produce a delicate plexus spun around the capillaries. The distribution of nerves is richer in the convoluted and narrow than in the straight collecting tubules.

Dr. Lafont, in a paper read before the Société de Biologie of Paris in 1885, stated that the administration of nitrous-oxide gas always produced albuminuria. Chloroform, as regards its effect on the kidneys, seems safer than ether. I believe ether to be productive, when administered in nephritis, of a double source of danger; first, the production of paralysis of the renal nerves and their terminal filaments, leading to passive congestion, or inflammation of the renal vessels, glomeruli, etc.; and second, the impossibility, on the part of the kidneys, of the elimination of the ether, and its consequent retention in the system.

Chloroform is, I think, much safer. I have many times resorted to it in uræmic convulsions occurring in the puerperal state. and almost always with benefit; never, as yet, with any unfavorable consequences. The experience of many other—indeed, I believe, of most—physicians has been equally favorable.

Chloroform is, however, administered in operations much less frequently than ether, and I do not think that we are to pronounce its use in chronic nephritis absolutely unattended with danger. What evidence is there, for example, that some of the deaths after its administration may not have been owing to disease of the kidneys?

Fortunately for patients afflicted with renal disorders who suffer from conditions which are dependent upon the knife or upon surgical interference for relief, the skilful local application of cocaine has proved a sufficient anæsthetic in many severe cases.

The literature pertaining to the administration of ether when nephritis exists is not extensive. Among the most important articles are the well-known papers of Dr. Turnbull, of Philadelphia, published in 1880, and of Dr. William F. Norris, of Philadelphia, published in 1881, to which I may add an able paper by Dr. Wesley M. Carpenter, of New York, published in THE MEDICAL RECORD, February 6, 1886, valuable both as containing much original matter and as a *résumé* of what has been written.

If I have given the details of this case with some prolixity, it is because I have wished to do justice to the length and breadth of a common condition of mild albuminuria, apparently of small dimensions, but capable, when aroused by ether, of assuming very gigantic proportions and producing dire results.

HOW TO ABORT A FELON.—Dr. John T. Metcalf writes to the *Boston Medical and Surgical Journal*: "My father was a medical man, who graduated from the University of Pennsylvania in 1816 or 1817. In 1839 I learned from him that a felon could, if seen early enough, be made to abort by wrapping the finger-end with narrow strips of adhesive plaster. When pus has been formed, I learned twenty years ago, from a country doctor, that immediate relief and speedy cure would follow the gentle, slow separation of the nail from its envelope by means of a penknife blade, not too sharp, at the point nearest the seat of greatest pain. Very soon a drop of pus shows itself, and relief comes. I am aware that the plan described is known to many medical men. It was not known to me at the time referred to, when the country doctor showed me how to treat a paronychious patient, whose finger I was about to lay open by the 'free incision down to the bone, taught in the lessons of my great masters."

INTESTINAL CALCULI.—Dr. Hockenhull reports in the *Atlanta Medical and Surgical Journal* a case of a boy who was suffering from tenesmus. Examination of the rectum showed a mass of small hard stones, forming a complete wall, obstructing and distending the bowel. The stones were of a black color, and of a hard, flinty nature, and varied in size from that of a pea to that of the end of the little finger. According to the father's account the total number of stones extracted at the time and passed subsequently was four hundred and two.

Clinical Department.

PARANOIA.

Dr. Philip Zenner, of Cincinnati, reported the following case at a meeting of the Cincinnati Academy of Medicine, held on December 20, 1886: The patient was a married lady, twenty-eight years of age, who had always been in good health, never had uterine disease, and was always regular in her menstrual periods. There was no nervous disease in the family, but both parents and a sister had died of phthisis. She had always been apparently of sound mind, but since the death of her sister had been morbidly apprehensive of becoming herself consumptive, and hardly a month passed in which she did not consult some physician in regard to her lungs. A few days after her second confinement, which had been an easy one, she suddenly thought that she was dying, although there was absolutely nothing abnormal in her condition. Soon after leaving her bed, after this confinement, she began to have delusions that her neighbors were looking at her in a peculiar way, were talking about her, and wanted to injure her and her child. She insisted on moving away from the neighborhood, and was never thereafter content to stay long in one house because of her suspicions of her neighbors. She grew careless about her household affairs, and began to spend money lavishly. She also seemed to become weak in her will-power, and was unable to come to a decision in any matter. Her youngest child died three years after this change in her mental condition, and she grieved a good deal and grew worse rapidly. She now began to have suspicions that some one was trying to poison her by putting cannabis indica in her tea. When Dr. Zenner first saw her he tried to draw her attention to her physical condition, but though her memory and judgment seemed good in other matters, it was impossible to draw her mind away from her delusions or to persuade her that her suspicions were unfounded. She soon after attempted suicide, and was then removed to an asylum. She now has more constant hallucinations, hears voices, and believes that everyone who comes to the asylum desires to see her. Many prominent people, she thinks, are trying to liberate her; numbers have sent her presents of diamonds and costly apparel. There are several features of this case to which the author directed particular attention: 1. The absence of heredity or other predisposing causes. 2. An antecedent condition of slight hypochondriasis. 3. The special kinds of delusion—delusions of observation, of persecution, and of grandeur. 4. All the delusions have a certain logical basis; the basis is faulty, but the delusions follow logically from them.

The case reported was a typical one of paranoia. The most common order of development of symptoms is, first, hypochondriacal sensations; second, delusions of observation; then, delusions of persecution; and, finally, delusions of grandeur. The author then explained the origin of these delusions, and how one naturally grew out of the other. The delusions vary according to the subjective condition of the patient and his surroundings. One with hypochondriacal sensations about the genitalia is likely to have delusions of a sexual cast. One living in a monarchy is likely to believe himself to belong to the royal family, in a republic to be a statesman, reformer, etc. Some of these patients have great intelligence, which they continue to manifest after they have the disease; the majority are above the average intelligence. The disease occurs most frequently in those with a hereditary taint of insanity. There is often, in addition, asymmetry of the skull or other irregularity, indicating a personal predisposition to nervous diseases. The disease often breaks out at great physiological periods, as puberty, etc. It is sometimes caused by great emotional strain, injury to the head, and acute febrile affections, etc. The cases are often the source of great difficulty in diagnosis. The disease may be entirely overlooked. They are the kinds of cases which cause the most trouble in courts of justice. The diagnosis must be based especially on the logical basis of the delusions. The character of the delusions may be of value as pointing to the true disease. The author reported a case in which he was led to a diagnosis of paranoia by the fact that the patient was suspecting his friend of ill-treating him.

Mistakes are often made in supposing cases to be mania or melancholia on account of a gay or sad demeanor. The paranoiac may be either cheerful or depressed, according to the character of his delusion. It is often very important to make a correct diagnosis, because the prognosis in mania and melancholia is much better than in paranoia. The author reported two cases of his own in illustration of the importance of a correct diagnosis.

Paranoiacs often become addicted to drink, and then the alcoholism is likely to mask the real disease. The author reported such a case. The man, who had been sent several times to the asylum, and detained a few weeks as a case of alcoholism, shot at and wounded a man, an act to which he was prompted by his delusions, shortly before the author saw him. This would not have occurred if the true disease had been recognized and he had been kept in the asylum. The prognosis of paranoia is generally unfavorable, though the disease may be at a standstill for years.

The treatment should be of a tonic character.

EPITHELIOMA OF THE AURICLE.

Dr. J. W. Kales, of Franklinville, N. Y., reports the following case to prove that epithelial cancer in this locality may be of most malignant type, and that caustics are often most inefficacious in the treatment of the affection: "T. K——, sixty-five years of age, his father, grandfather, and some others in the family had died, and a brother has since died, of cancer. I cannot give further particulars of these cases. T. K—— first noticed a small scale on the upper portion of the helix of the left ear. From time to time scales were removed, and the cancer doctor applied his caustics. The disease was not cured, nor did the caustics do more than stimulate the growth. The application of the knife was refused. The growth of the epithelioma continued for about five years without affecting the health of the patient. Then it suddenly commenced to grow very rapidly. In two months the whole auricle was involved, and the disease was extending along the external auditory canal. The patient rapidly declined in health. The cancer in a few weeks involved the middle ear, and death claimed its victim. I have seen a large number of cancers, but I never saw one do its deadly work more rapidly than this epithelioma of the auricle."

HERNIOTOMY UNDER COCAINE.

Dr. Albert F. Fuchs, of Fredonia, Wis., writes: "Articles on operations under cocaine are so frequent as to have become tiresome, but I will, nevertheless, venture to contribute another to the vast number. On December 8th I operated on an incarcerated femoral hernia, in a man aged seventy-five years, under local anæsthesia by cocaine. Without going into details regarding the operation, I may be excused when I claim that it was quite difficult. The impediment to reduction was threefold, *i.e.*, an hour-glass constriction of sac, bands of fascia about the neck, and the femoral ring. The gut had been out, and there had been no movement of the bowels for eight days; pain and tympanites had been persistent and increasing for six days. Cocaine solution was applied with a Squibb's graduated pipette to the skin, and injected at numerous points into the cellular tissue. It

was used but once, and in all seventy minims of a four per cent. solution was consumed. The operation was painless, with exception of skin sutures, which were inserted two hours after the application of the cocaine. Recovery was typical of aseptic surgery. In this case local anæsthesia with cocaine was employed, not for the novelty of the thing, but because general anæsthesia was inadvisable. The old man had been suffering for years with putrid bronchitis, the discharge sometimes amounting to twenty-four ounces and over in a day. Momentary dyspnœa was very frequent and aeration of blood insufficient. The idea of giving ether or chloroform in such a case was not pleasant. I do not know, and it is immaterial, whether mine is the first herniotomy under cocaine; and it is hardly probable that I can claim priority of suggestion and use on patients suffering with putrid bronchitis and bronchial dilatation. I may be wrong when I claim that bronchiectasis is a contra-indication to the use of general anæsthesia; theoretically, I should judge it is."

SECONDARY SYPHILITIC INOCULATION OR CONTAGION.

Dr. J. J. Cassidy, of Toronto, writes: "In eighteen years' practice in this city I have treated two cases of chancre on the lip. Both patients were respectable young girls. The history of the first case is as follows: H. S——, eighteen years of age, Canadian, was brought to my office by her mother, to be treated for an indurated sore, situated about two lines below the red margin of the lower lip. The cervical glands were enlarged and tender. Dr. J. E. Graham, of this city, saw the case with me, and pronounced the disease a true chancre. Anxious to learn the cause of the disease, I questioned my patient as to her relations with gentlemen. She informed me that she was receiving attentions from a young man to whom she was engaged to be married. I asked if her affianced was of good constitution. She replied in the affirmative, and stated that she never knew him to be ill; but that, owing to overwork at the shop, he occasionally felt weak and was taking a tonic. I obtained a sight of the prescription, and, as I expected, the principal preparation in the formula was iodide of potassium. I then asked my patient to request her affianced to call at my office. He came. I informed him of my suspicions, but he denied having had any improper relations with women. His penis was free from disease. He had, however, a number of mucous patches on the inner surfaces of the lips and cheeks. He acknowledged having frequently kissed my patient, but stated that he had no idea that poison could be conveyed from his mouth, as he supposed his sores to have been caused by his habit of holding zinc nails in his mouth when working at his trade. I treated the patient for some months with mercurials, and learned subsequently that the pair got married; but their subsequent history has not reached me.

"M. C——, aged nineteen, Canadian, was receiving attention from a young man, and consulted me for an indurated sore, situated at the edge of the red margin of the lower lip. The cervical glands were enlarged and tender. In this instance I was unable to secure the attendance of the donor, and cannot therefore describe the state of his buccal mucous membrane. The young lady, however, stated that he had been taking mercury, and that he had a tender mouth. Mercurials were used in her case until the disease was cured. I cannot say whether these cases were instances of inoculation or contagion. I questioned both patients on this point, but neither of them remembered having had a pimple or an abrasion about the mouth previous to the appearance of the chancre. The presumption would therefore be in favor of contagion. I do not, however, consider the evidence conclusive. The same difficulty must surround the origin of chancre in the male. Not every man who presents himself with a chancre can say for certain that he had no abrasion of the surface of the penis before or during coitus. Everything considered, it is hard to say how the bacillus of syphilis effects an entrance into the body—whether it goes to the blood directly through an abraded surface, or through the lymphatics, or through both these channels. It is certainly, however, more reasonable to attribute syphilis to inoculation than to contagion. The interesting point for practitioners to know is that syphilis may be communicated from secondary lesions. A patient under treatment for syphilis should therefore be informed of this fact by his physician."

A FATAL CASE OF POISONING FROM CAMPHOR.

Dr. Mary J. Finley, of Mansfield, O., sends a report, read before the North Central Ohio Medical Association, of a case of camphor-poisoning. It is asserted that no undoubted fatal case of poisoning from this substance has ever been recorded. The writer states that she has been able to find reports of but two cases in which death was presumably due to an overdose of camphor. One was in a feeble infant, to whom thirty grains of powdered camphor had been given as a vermifuge. The second case was that of a woman, forty-six years of age, who took 184 grains in order to produce abortion. The abortion was produced and the patient died. The smallest dose known to have produced alarming symptoms in an adult is 20 grains; the largest dose recovered from is 160 grains. The following is the case reported by Dr. Finley: "On August 5, 1886, I was called to see a child, aged two years, and found it in violent convulsions. About an hour before that time the mother had heard it cry out in the adjoining room, and the child met her in the door, crying that its mouth was burned. A bottle which had contained an alcoholic solution of camphor lay on the floor; some of the liquid was spilled on the carpet, and the front of the child's dress was saturated with it. After taking a drink of water and having its mouth washed, the child made no further complaint, and appeared to be perfectly well. But in about half an hour it suddenly fell over in its mother's arms, apparently unconscious. It remained quiet for a while, when convulsive movements began, slight at first, but increasing in violence until I saw it. At that time the breathing was noisy and rapid; pulse 180, but not weak; skin moist and pale, but warm. The breath smelled strongly of camphor. I immediately ordered a warm bath, and while that was being prepared gave an enema of bromide of potassium and chloral. While the patient was in the bath the convulsive movements moderated, until there was only a spasmodic jerk of the right arm and side of the chest at intervals of several seconds; this was accompanied by spasm of the diaphragm. In half an hour the convulsions again became general, and the hot bath was repeated; bromide was again given in strong coffee by enema. The movements moderated as before, and finally ceased. Two and a half hours after the ingestion of the poison the child was comatose; breathing slightly sterterous, but normal in rapidity; pulse 100 and of good strength; skin natural in color, warm, and free from moisture. At this time Dr. A. J. Erwin saw the case with me. The child looked as though it was in a natural sleep; and from all previous experience with camphor-poisoning, and from the teaching on the subject, there was every reason to expect that the coma would pass into that condition, and the child would awake convalescent. But in less than an hour the convulsions returned with redoubled fury, and continued unabated until the little fellow expired. Death occurred in about four hours from the time the camphor was taken. The temperature during the final convulsion ran up rapidly. Immediately after death there was a free watery evacuation of, apparently, the enemata which had been ad-

ministered, and which had not been absorbed. The attempted medication by the rectum had, in all probability, no influence whatever on the course of the symptoms. The child could not swallow at any time after I saw it. I was told that it had vomited before my arrival, but the mother afterward informed me that it had not done so. The amount of camphor taken cannot be known with certainty. The mixture from which the child drank consisted of 15 grains to a drachm of sixty per cent. alcohol. It is not to be supposed that the child would take more than a single mouthful of this fiery liquid, and that it swallowed all of that is extremely improbable. It is strongly probable that the child did not swallow more than a drachm of the solution; if so, death occurred from 15 grains of camphor."

NOTES ON ANTIFEBRIN.

Dr. J. L. R. Wadsworth, of Collinsville, Ill., reports the following case, showing the results obtained by antifebrin in malarial fever:

"I received a telegram, calling me to the bedside of my daughter, in Kansas City, Mo., November 23, 1886, and found her suffering with an attack of continued malarial fever, that had reached the twenty-third day, under the excellent care of Dr. Schauffler, of that city. Dr. Schauffler had considered the case a mild one up to the twentieth day; but at this time the conditions were more serious. Temperature now ranged from 101.8° to 104.9°; pulse, 104 to 120; patient restless and sleepless. Medicine now failed to meet expectation. Quinia raked the stomach, not only in antipyretic, but in tonic doses. Antipyrin was followed by great depression, and with but little effect upon the temperature, although its previous use in this case had given the best results. These remedies had to be abandoned; and frequent spongings with water, and the internal administration of peptonoids, milk and whiskey, iron, ergot, and bromidia, were resorted to, to meet indications, with, however, but slight improvement for a few days. On the thirty-fifth day heart-failure threatened early dissolution. Thorough alimentation and stimulation were now pushed. Peptonoids (beef, milk, and gluten), ʒ j., with McMunn's Elix. opii, gtts. v., every four hours, alternated with whiskey, ʒ j., with tr. ferri chlo., gtts. xv., slightly broiled beef (which was relished) and water-toast, as would be taken by the patient. On the thirty-seventh day there was still no change for the better; the temperature was 104.2°. Pulse weak, irregular, and very compressible (so much so that it was with much difficulty counted), and ranging from 120 to 148. Dr. J. D. Griffith was asked to unite with us in the management of the case, and on the second visit suggested the use of antifebrin—a remedy entirely new to us, of which he had recently procured a small sample while in New York City, at the suggestion of Dr. A. A. Smith, who assured him that it could be given under the most unfavorable conditions of the heart's action; and we decided to use it. I gave it with the greatest care, accompanied by hourly observations of the temperature and pulse. Throughout the time of its use no change was made in the treatment last indicated, with the exception that, as on the thirty-eighth day, a slight exacerbation of fever, followed on the thirty-ninth day by a decided one, was noted. Quinia was administered at first hypodermatically, and later by enema. I could observe, however, no effects on the temperature from its use, but the exacerbations ceased.

It would seem, from the data obtained in this single case: First, that antifebrin in five-grain doses reduced the temperature as promptly as either quinia or antipyrin had previously done in this case.

Second, that, notwithstanding the very unfavorable conditions for exhibiting antipyretics, such as we have so far been familiar with, antifebrin gave no evidence of any depressing influence upon the system.

Third, that the effect of a dose of five grains upon the temperature commenced in about one hour from the time of administration, and continued for from three to seven hours, averaging a little less than four hours.

Fourth, that temperature was lowered from 1.3° to 4.5°, averaging a little over 2°.

Fifth, that the pulse-rate was lessened proportionate with the fall of the temperature, following the latter about one hour, both at commencement and termination.

Sixth, that the pulse-rate was lessened from two to sixteen beats, averaging about six.

Seventh, that recurring exacerbations of fever disturb the action of antifebrin; and, in the above conclusions, I have tried to eliminate the results of this disturbance, and enumerate only its effect on the fever without the marked exacerbations.

Finally, fully recognizing that "one swallow does not make a summer," I still offer this observation to the profession, with the hope that others may be led to investigate the drug, and more fully determine its value; and if it should be proven to be a non-depressant antipyretic, it will rank among the most valuable drugs which we possess.

CASE OF INVERSION OF THE UTERUS REDUCED, EIGHTEEN HOURS AFTER ITS OCCURRENCE, BY NOEGGERATH'S METHOD.

Dr. Alonzo Pettit, of Elizabeth, N. J., reports the following case: Mrs. W. G——, aged thirty, was attended in her second confinement by Dr. ——. The labor was natural, and occupied about twelve hours. Two half-drachm doses of fluid extract of ergot were given before the birth of the child, and another before the delivery of the placenta. At the close of labor the uterus was found inverted in the vagina. The patient was in a state of collapse from shock, so that efforts at reduction were not persisted in.

Under the use of stimulants reaction was established, and after the lapse of eighteen hours the operation of reduction was performed—present, Drs. Schleimer, Hough, and Crane.

The patient being etherized, the writer introduced the right hand into the vagina, grasped the uterus, and squeezed it firmly for a few minutes. In this way a good deal of blood was expressed from its sinuses; the uterus was considerably reduced in size, and its walls were rendered softer and thinner. It was then found that an indentation could be easily made in the region of the left cornu. This was gradually extended to include the fundus, and the reduction was then completed without difficulty. Counter-pressure was made continuously with the fingers of the left hand into the ring of the os, above the pubes. The time occupied was about twenty minutes. The recovery was complete, and was not attended by any unfavorable symptoms.

THREE CASES TREATED BY INHALATIONS OF OXYGEN GAS.

Dr. L. C. Winsor, of Spirit Lake, Ia., reports the following cases: Case I.—A boy, aged eighteen months, was suffering from a severe attack of laryngismus stridulus and chronic bronchitis. The child was weak and anæmic, and seemed to be of a strumous diathesis. Cod-liver oil inunctions were made twice a day, and syrup of the iodide of iron, bromide of sodium, iodide of potassium, and lactopeptin were given internally. This treatment was varied somewhat during two months, but was on the same general line. The child had a fair appetite, but did not gain in flesh or strength. All medicines, except cod-liver oil, iron, and pepsin, were now discontinued, and inhalations given of equal parts of oxygen and nitrous oxide. The first night following this the patient slept much better than for two months before, and he began

from this time to regain his strength. At the end of six weeks he was in very good condition, the lungs were normal, appetite and digestion were good, and there had been a marked increase in flesh and strength.

Case II.—A woman, aged thirty-four, had been for several hears in delicate health, and had trouble at the apex of the right lung. Upon being called to see the patient, Dr. Winsor found her suffering severely from dyspnœa; the respirations were 57 per minute; pulse 120, small and weak; temperature 99.5°. Physical examination revealed the presence of a capillary bronchitis in the lower lobes of both lungs; mucous râles were heard over the upper lobes, and there was dulness over the lower lobes, and in some cases flatness. The patient had been suffering from dyspnœa for tweve hours, and was gradually growing worse. She was unable to lie down or to walk across the room. Commencing cyanosis was present. Inhalations of pure oxygen were begun at once, and at the end of five minutes, after three inhalations of five breaths each, the patient became easy, the breathing was slower, pulse slower and fuller, and the cyanosis disappeared. Whiskey and carbonate of ammonia were given, a hot flaxseed poultice was applied over the chest, and inhalations of oxygen were given every fifteen minutes. At the end of eighteen hours the inhalations were reduced to once an hour. Two days later the patient was very comfortable and much stronger. Physical examination showed almost entire absence of râles over the upper lobes, the dulness was less marked over the lower lobes, and the chest was expanding well. Respiration, 23; pulse, 80; temperature, normal. The patient continued to improve and made a good recovery.

Case III.—A young woman, nineteen years of age, who had been subject to severe headaches, biliousness, and constipation, came under treatment for anæmia. There was extreme pallor of the face, lips, and conjunctiva; the pulse was 120; a loud anæmic murmur was to be heard in the neck; the patient was weak and suffering from headache and nervousness. Inhalations were given of a mixture of equal parts of oxygen, nitrous oxide, and air, and tincture of iron and Fowler's solution were also ordered. The inhalations were practised twice a day, five breaths being taken each time. In two weeks the patient was feeling very much better. The murmur had disappeared, the lips and face were of a healthy color, and the headache and nervousness were but little complained of.

Dr. Winsor reports that he has also two cases of pulmonary phthisis in the second stage now under treatment by inhalations of oxygen and nitrous oxide. Both patients have gained in flesh and strength, but they have been under observation for too short a time to enable him to say whether the improvement will be permanent or not.

A CASE OF EARLY DENTITION.

Dr. L. C. Winsor, of Spirit Lake, Ia., reports a case occurring in his practice, of a boy, aged seven weeks and six days, who has already cut the canine tooth in the upper jaw on the right side, the corresponding tooth on the other side is almost through, and the gum over the two central incisors of the upper jaw is swollen, and the teeth seem about to appear. The father and mother are both healthy, and at the time of conception the father was in the habit of walking sixteen miles every day. The diet of both consisted of ordinary food, with the exception of more fruit than is usually eaten. During the latter part of gestation the mother ate oatmeal in considerable quantities. Both father and mother lived in the open air (he being a civil engineer) a greater part of the period of gestation. The child is very healthy in every respect, although he is being fed with the bottle. Dr. Winsor adds that he would be glad to be informed of any similar cases on record.

A CASE OF ACUTE INDO-CYCLITIS WITH PERSISTENT INCREASED TENSION SUCCESSFULLY TREATED BY "BADALL'S" OPERATION.

Dr. A. P. Gilmore, of Chicago, Ill., reports the following case: Mr. J. R., aged thirty-five, presented himself at the Eye and Ear Infirmary, August 10th, suffering from a severe attack of what seemed to be idiopathic indo-cyclitis of the left eye. He had never had sore eyes before. There was considerable pericorneal injection, pain over the ciliary body, augmented tension, severe pain, annoying lachrymation, photophobia, and blepharospasm. The usual treatment was adopted, atropine alternating with eserine and massage, leeches, hot water, and anodynes. The eye did not improve, the pain grew worse, and the tension increased. As he had suffered with syphilis ten years ago he was placed on anti-syphilitic treatment, but with no relief. Opiates were given at night to produce sleep. This treatment was continued three weeks, with only occasional relief, followed by renewed exacerbations.

I suggested to him, with some reserve, Badall's operation, to which he readily consented, and the operation was performed without an anæsthetic. The result was most gratifying; the pain subsided, the tension diminished, and the patient slept that night without narcotics.

The next day both subjective and objective symptoms were much improved. I discontinued all other treatment excepting the atropine, which was continued for four days after the operation. On the tenth day the patient was discharged cured, with normal vision. He was seen again on December 1st, and states that his eye has been perfectly well since the operation.

"Badall's" operation consists in neurectomy of the nasal branch of the trigeminal nerve, and is employed by the originator for persistent and painful increased tension in glaucoma. The results of the operation are due to reflex action on the eye through the branches of the fifth nerve. The operation has been indorsed by Abadie in his observations on glaucoma, and adds one more to the class of anti-tonic operations, such as sclerotomy, iridectomy, paracentesis, etc.

Bicarbonate of Sodium in Tonsillitis.—Some years ago Dr. Giné y Partagás proposed the local use of sodium bicarbonate in acute amygdalitis, and claimed that the drug was of great utility in the abortive treatment of this affection. Dr. Rovira y Oliver has republished, in pamphlet form, a series of articles bearing on this subject, which appeared in different issues of *Gaceta Médica Catalana* during the past four years. He reports a number of cases of simple catarrhal and parenchymatous tonsillitis in which a thorough trial of this remedy was made, and his conclusions are not wholly in accord with those of Dr. Giné. He thinks that in certain cases local applications, made every two or three hours, may prove of service in shortening the duration of the disease, but that the remedy cannot be considered in any sense as abortive of the inflammation. And very frequent applications, every five minutes, as recommended by the proposer of the method to cut short the disease, Dr. Rovira believes to be positively injurious rather than beneficial.

Students in the Italian Universities.—During the winter of 1885–6 there were 14,633 students in the universities of Italy, of whom 3,894 were at Naples, 2,073 at Turin, 1,216 at Rome, 1,163 at Bologna, 1,008 at Padua, and 1,005 at Pavia. The other universities had less than 1,000 students each, and at Ferrara there were but 39. Of the total number 5,195 were students of medicine.

A Dispensary in Kabul.—The Amir of Afghanistan has established a dispensary in the city of Kabul, and has placed it in charge of Dr. Abdul Kadir.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, January 29, 1887.

THE COMPARATIVE DIGESTIBILITY OF THE DIFFERENT NITROGENEOUS FOODS.

THE subject of food is one of perennial interest, and anything new bearing upon it is sure to receive attention. Certain experiments recently made by Dr. J. W. Fraser upon the comparative digestibility of the different albuminoid bodies are *à propos* of this remark. He found first, experimentally, that the different substances—serum albumen, egg albumen, myosin, syntonin, casein, and gluten—varied considerably in their digestibility when acted upon by peptic or pancreatic solutions. Further tests were made, therefore, to determine the exact amount of these differences. The substances were taken in amounts of about two grammes, and were submitted to an artificial digestive process for six hours at a temperature of 100° F. The percentage of the substance digested was determined by dialysis.

The experiments showed that serum and egg albumen head the list in digestibility by pepsin (1.97 and 1.96 per cent.); next came syntonin, or acid albumen (1.25 per cent.) (made by submitting raw beef to a dilute hydrochloric-acid solution); myosin, raw and cooked, was quite high in the scale also (1.03 and 1.04 per cent.); while cheese (casein), cooked albumen, and vegetable albumen, or gluten, stood at the bottom (0.47 to 0.60 per cent.). Cooked myosin ranked at the head in pancreatic digestion, while the raw albumens of serum and egg came next.

Some experiments were made also with beef-tea, with and without the addition of albumen. The main outcome of the experiments was to show that the raw albumens are the most digestible of the albuminoid proximate principles, while myosin, in the form of beef-tea, ranks high. On the other hand, casein, gluten, and cooked-egg albumen are much less digestible.

The pancreatic juice acts especially well on raw albumen, and on acid and alkali albumen. Hence in fevers, when the gastric juice is secreted in very small amount, while the pancreatic gland continues active (Sir W. Roberts), raw albumen, syntonin, or alkali albumen, may be given alone, or in beef-tea. Milk ought to be a rather better food in fevers than in a febrile state in which there is gastro-intestinal dyspepsia.

In adynamic states beef-tea, to which the white of an egg is added, or soup containing syntonin may be used. Dr. Fraser says:

"The experiments with casein and gluten appear to show that there are very few worse foods for a delicate stomach than the usual bread and milk, for, as has been seen, the stomach only dissolves about 0.6 per cent. of these principles in the same time that it dissolves nearly two per cent. of serum-albumen. And the casein in the experiment was in an easier form for digestion than that in which it is usually presented to the stomach, for, as used, it was in a fine granular form, practically freed from fat with alcohol and ether; while cow's milk in the stomach forms dense solid clots, rendered all the more insoluble by the fat, which forms the greater part of their bulk. True, the bread acts as a diluent to the clots, breaking them up, with passages for the gastric juice; but still it is evident that, for digestion by a delicate stomach, bread and milk does not form an ideal food. Whey contains lact-albumen, which is the same as serum albumen, and it is a mildly nutritive food."

QUACK ADVERTISEMENTS AND THE RELIGIOUS PRESS.

WE have often called the attention of religious papers to the gross deception which they encourage by allowing "never-failing cures," "warranted never to fail," etc., to appear in their advertising columns. All these journals may place it upon their records as one of the things proved, that when medical men read such advertisements in religious papers, they conclude that it is more the love of money than the love of truth that influences them, and that these papers are wearing the cloak of hypocrisy.

The Christian Advocate, one of the most influential papers of the Methodist Episcopal denomination, has allowed in its advertising columns the statements that a certain medicine "never fails to give almost instant relief," "is unsurpassed for the relief of," "stops more surely and thoroughly than any other medicine," and other similar expressions, all of which can be found in the deceptive advertisements of the most blatant quacks and pretenders.

Upon the first page of the same number we find the following words: "We ask our readers to turn a deaf ear to those who would induce them to give up *The Christian Advocate* for other papers in or out of the Methodist Episcopal Church." To this we would add, without reference to the mercenary pleading: "The influence of the paper would be greatly promoted were its advertising columns absolutely *pure*." There is no good reason why they should not be. We also find in the same number: "It is a safe rule to beware of all correspondents who offer to do anything *free*, unless they are known to be responsible; and an equally safe rule to put no confidence in correspondents and advertisers who *do not tell the whole truth* in the advertisements."

Again, in the same number we find a noteworthy criticism of one of our daily papers for publishing the indecent proceedings of a notorious divorce case, and in it the following language was used: "Things will go on as bad as they are, or, rather, they will grow worse, until every time decent men and women see indecency in the paper they regularly take, they will send a protest. These should be showered in by the hundred, and by the thousand, and if no change takes place the paper should be dropped." We heartily urge that this advice be applied

by all medical men to all religious papers that publish advertisements of patented and proprietary medicines worded in a way which will *deceive the people.*

For an honest and educated physician cannot be found who will not say, without hesitation, that expressions such as we have quoted above, when applied to any known remedy, have no foundation whatever in truth. To harbor them is to deceive; to practise deception is wrong; to continue to practise it after attention has been called to the error is inexcusably wrong; and the papers continuing it should be rebuked in the way recommended by *The Advocate.*

THE STATISTICS OF SEWAGE AND SEWER-GAS.

Sanitary science concerns itself with some very odd data, which affect the imagination in a manner almost precisely opposite to that produced by idyllic verse. Dr. Tidy, for example, states that 10,000 people pass 600,000 fluid-ounces of urine, and one ton of moist fecal matter daily. Upon this basis it follows that the good people of New York City discharge yearly the Niagarous volume of 173,375,000 gallons of urine, and 50,000 tons of fecal matter. This would be worth to agriculture between two and three millions of dollars; since each man's annual income, simply from his emunctories, is estimated at from $1.50 to $5.00. This is often more than the total annual income from the first years of professional practice.

The sewage of a city contains not only excrementitious matter, but the water from washings of all kinds, vegetable matter, etc. The amount of sewage to each inhabitant is estimated to be 24 gallons daily. For this great city, which believes itself above the average in most things, the total annual sewage amount cannot be less than eleven billion six hundred and eighty millions of gallons. This immense stream of liquid filth flows beneath our city and empties itself into the sewers on each side. In its passage gases of fermentation and putrefaction are generated. The amount varies greatly with the season, the rainfall, etc., and the anosmic statisticians who delve into these matters hesitate to give us any averages here. According to some estimates, however, there are 800,000,000 cubic inches of sewer-gas developed in the sewers daily.

This sewer-gas (in Paris) is found to be composed of carburetted hydrogen, 72.88 parts; sulphuretted hydrogen, 6.70 parts; carbonic acid gas, 12.30 parts; carbonic oxide, 2.54 parts; miscellaneous gases, 5.68 parts. Micro-organisms are also present in it.

Such gaseous mixtures are, of course, not healthful, but, on the other hand, are not seriously injurious to health when quite well diluted, as is the case when the mixture escapes into houses. In large amount, or if continuously inhaled for a long time, languor, anorexia, headache, slight febrile movements may result. The men who work in the sewers of Paris and London are, however, quite up to the average in health.

When, through obstruction of sewers, the sewage matter accumulates, its gaseous emanations are likely to become much more poisonous, probably because it becomes a nidus for the development of pathogenic organisms. In fact, sewer-gas is probably a seriously poisonous substance only when it has been infected with specific germs.

NIAGARA FALLS AND THE INTERNATIONAL CONGRESS.

It is curious to observe with what unanimity all our European exchanges speak of Niagara Falls in connection with a trip to this country next summer. The impression seems to be that, if the Congress is not a large one, the Falls will abundantly make up for it, and that any lack of national representation at Washington will be fully set off by the thoroughly American way in which the water goes over Niagara. We have no doubt that the Falls will do themselves credit, irrespective of ethical differences or geographical misrepresentations. And we are quite sure that our visitors will find that, in the line of precipitous aqueosity, they quite outdo anything in decaying Europe. We do not like, however, to have it thought that Niagara Falls will be the sole salve for possible scientific disappointments. The Falls really are only one hundred and sixty feet high, and are composed only of plain water. One-half is in Canada, and is necessarily somewhat provincial in its style of precipitation.

Let us assure our coming guests that, aside from the Congress and the Falls, we will have other curiosities to present equally capable of making the trip an agreeable and instructive one.

A NEW SYMPTOM IN TUBERCULAR MENINGITIS.

Dr. J. D. Skeer, of Chicago, has recently made a communication to the Pathological Society of that city, in which he claims to have observed a new and pathognomonic symptom of tubercular meningitis. It is, he says, always present in the first or second stage of that disease, and consists of the appearance of a small whitish or yellowish-brown circle, which forms in the iris near to and completely surrounding the margin. When it begins to appear it is indistinct, and resembles a wreath of thin white clouds, the edge of which extends to the free border of the iris. In from twelve to thirty-six hours the whole margin of the iris will be involved, having become of a whitish or yellowish-brown color, and appearing irregular, thickened, and somewhat granular. The changes occur in both eyes simultaneously. They are more apparent in irides of a brown color. The cloud-like appearance is sometimes very evanescent, hence the iris must be frequently examined. In cases of primary tubercular meningitis the circles appear early, but in cases in which there is originally a simple inflammatory change, with tuberculous deposits later, the circles are not seen until the second stage of the disease. Whenever it appears, according to Dr. Skeer, the diagnosis of tubercular meningitis may be made with certainty. We do not understand it to be claimed that it always occurs. Dr. Skeer has observed this sign in twenty cases, in only two of which a post-mortem observation was made. This is a rather slender basis upon which to construct a pathognomonic symptom.

A committee appointed by the Society to report upon Dr. Skeer's paper gives the results of a correspondence with a number of ophthalmologists, including Dr. Marcus P. Halfield, Dr. Adolf Alt, Dr. H. Knapp, and Dr. Bock, of Vienna. None of these gentlemen seem to have observed exactly the appearance described.

In one case observed by the committee, and declared by Dr. Skeer to show the symptom in question, some

doubt is expressed as to whether the condition was not normal, or, at least, had not for a long time existed in the patient, a cachectic and scrofulous child. The question as to whether a syphilis may not be concerned in producing the appearance was not discussed.

Further observations upon this interesting point will, no doubt, soon be forthcoming.

VERY REPREHENSIBLE MEDICAL ADVERTISING.

Our esteemed contemporary the *Philadelphia Medical and Surgical Reporter*, in its issue of January 22, 1887, published the following startling announcement :

LOCAL CELEBRITY OF A NEW YORK MEDICAL EDITOR.

As Dr. Geo. F. Shrady, of New York, editor of the New York Medical Record, is such a stickler for keeping the names of his fellow-editors out of the newspapers, that we respectfully ask his explanation of the following felicitous tribute to his skill, printed in the *New York Tribune* of recent date :

" Dr. Geo. F. Shrady, of New York City, performed a noticeable surgical operation upon a young son of Mr. W. MacRussell, of Saugerties, N. Y., on Saturday last. The child's leg had been broken some time since, and it had become united so improperly that he had lost all use of it. The doctor removed a portion of the defective bone, and reset the limb successfully. Various prominent surgeons witnessed the operation. The patient is doing well."

Will not our brother-editor relieve us by stating that it was " without his knowledge " and " contrary to his wishes ? "

We simply answer that, although the operation was performed several years ago, and must have been noticed then, this is the first time that Dr. Shrady has seen the article, and the first time that he knew it had been written. Of course, it can easily be seen that the operation was not a very remarkable one. It simply consisted in sawing off the ends of an ununited fracture and wiring them together. We should like to be able to state that this operation was the first of its kind on record. Probably it was—from a newspayer standpoint.

TENEMENT-HOUSE REFORM.

There can hardly be too much done for the improvement of life in New York tenement-houses. At the very best, they furnish poor substitutes for homes, and the poor who live in them are constantly subject to social dangers and unhygienic influences. The attempts of the Sanitary Protective League, the *Morning Journal*, and of numerous public-spirited citizens, to secure amendments to the present tenement-house law, deserve the hearty support of the medical profession. The amendments provide that every tenement shall have a dry cellar, good drainage, ample water-supply, and a janitor ; that the owner's name shall be " registered ; " that a semi-annual inspection by the Board of Health of all tenements, and an annual report shall be made ; that free winter baths shall be furnished ; that there shall be electric lights in the tenement districts ; and that Leonard Street shall be cut through so as to open up the Mulberry Street " Bend." The last two points are not so essential or important, but a more rigid official scrutiny of the tenement-houses is certainly much needed.

Dry cellars, good drainage, and an ample water-supply will not bring about millennial conditions, but they are quite essential to progress in that direction.

The mightiest steps will only be made, however, when the tenement-house dwellers have learned the gospel of cleanliness and temperate living. Sanitary reformers are too apt to think that when they have furnished soap and towel, their unwashed protégés are at once made clean ; whereas, the fact is that there pervades in the tenement-house population a prejudice against wasting in ablutions good money and valuable time that might be devoted to whiskey, tobacco, beer, concert gardens, and rowdy excursions.

GRASS STAGGERS AND THE LOCO WEED.

Under the name of the " grass staggers " the writer of an article on cow-boys, in the *Cornhill Magazine*, has described a disease affecting horses in certain parts of Texas and New Mexico. In a recent communication in these pages Dr. J. W. Carhart gave some additional information concerning the symptoms and etiology of this curious affection. The prominent symptoms seem to be due, in part, to a loss of muscular co-ordination ; the ponies become weak and staggering, and a slight blow on the head of an affected animal causes him to rear and fall over backward. The animal falls away in flesh, and his coat loses its shining appearance, the hair becoming rough and of a dirty color. The brain as well as the spinal cord would seem in certain cases to be affected, as it is stated that the animals often become absolutely crazy. These symptoms are due to the poisonous effects of a plant known locally as the " loco " weed, so called from the Spanish word *loco*, meaning insane.

Dr. W. Thornton Parker, of Newport, R. I., who saw much of the disease while living in the Texas Panhandle as acting assistant surgeon in the United States Army, sends us a description of this plant. The weed does not grow as high as has been stated, but rather clings to the ground. The plant, even in winter, presents a bright, velvety appearance when all around is burnt up and dry, and the animals eagerly devour it. Dr. Parker writes :

" At a meeting of the Newport Medical Society, held October 6, 1885, I presented specimens of the loco plant, and such information as I then possessed concerning its history, and its poisonous effects upon horses. ' In view of the evident importance to the economical interests of that portion of the country, and possibly to medical practitioners also, that the plant should be still further investigated,' I was directed, in behalf of the Society, ' to bring the whole matter to the attention of the director of the Smithsonian Institution at Washington.' I procured several fine specimens from my friend Dr. Newton, of Mobutu, Tex. (assistant surgeon U. S. Army), and these were duly examined and reported upon. The loco plant is regarded by Professor Gray, of Harvard, as the *Astragalus legum*, a peculiar species of the vetch tribe, abundant in the region of the ' Texan Panhandle,' and agreeable to cattle and horses, but after having been used for some time by the latter, causing a special *madness ;* hence its name, from the Spanish loco. As a food its use renders *horses* valueless, and these seem to suffer most from this plant. It seems to have for them the fatal attraction that opium has for too many human beings. It has not yet been proved that cattle suffer very much, if at all."

The symptoms of the disease, as well as the description of the plant which is the apparent cause of them, recall the accounts given by various French and Italian writers of lathyrism. This affection presents the symp-

toms of a spastic paralysis of the lower extremities, the individuals having a markedly ataxic gait. The sensibility of the skin of the lower extremities is greatly increased, there is exaggerated patellar tendon reflex, and the ankle clonus is excited by the slightest movement of flexion of the foot. The plant, to the poisonous effects of which lathyrism is attributed, is also a species of vetch, the *Lathyrus cicera*. The disease attacks chiefly men, but horses have also been known to be affected. Vision seems to be disturbed in grass staggers, but in lathyrism the eyes are unaffected. The poisonous principle of the lathyrus has not been isolated, but experiments upon animals would seem to show that it resides in the healthy plant, and not in a mildew.

Lathyrism appears to be a curable disease. It sometimes subsides spontaneously when care is taken to exclude the vetch from the diet of the patient, and its disappearance may be hastened by the administration of bromide of potassium in large doses. Revulsive applications to the spine are said, also, to be beneficial. Possibly a similar plan of treatment for "locoed" ponies might be followed by good results, although there would be some difficulty in weaning them from their fondness for the poisonous weed.

QUALIFICATIONS IN SURGERY.

The impetus to surgery resulting from the adoption of careful antisepsis and more elaborate technique is producing results that are not altogether beneficial. The impression exists that capital operations, with the help of carbolic acid, can be done by almost anyone, and good obstetricians are turning themselves into poor laparotomists, skilful general surgeons are becoming restively anxious to undertake every kind of difficult abdominal surgery, and young men without special training are boldly undertaking the removal of the viscera and of visceral tumors. The operations of hysterectomy, nephrectomy, gastrotomy, pneumotomy, are in fashion, and a necessity is felt of keeping "in the swim." The result is, we fear, many disasters that are but little heard of, but which are helping to diminish greatly the beneficent results of modern surgery.

The fact is, that some natural aptitude and a great deal of special care and training are required to secure success in difficult capital operations. There are many persons not fitted by temperament or physical qualifications to do such work, but who yet are drawn by a feeling of ambition or false pride into pursuing it.

It would be better for surgical science and suffering humanity if some selective process could be applied to this matter. We do not advocate the creation of specialists who shall do such lines of work alone. This is unnecessary, and it would narrow and cripple the surgeon's art. But it is most desirable that some special qualification be shown before surgeons or physicians be allowed by professional sentiment, at least, to undertake those serious capital operations which are not required by emergencies, but through the slow progress of disease. Our schools give no special training in this direction, although they try to teach several other specialties qualifications in which are much less necessary to the saving of human life. It is time that educational institutions took up this matter.

News of the Week.

A Rare Book.—Dr. Alexander Hadden, of this city, has just become the possessor of a rare book, "The Herball, or Generall Historie of Plantes," by John Gerarde, surgeon, printed in London in 1597. It is a work of 1,392 pages, exclusive of copious indexes, etc., and contains upward of two thousand wood-cut illustrations of trees, plants, fruits, and flowers, which are remarkable for their excellent drawing, as well as for their number. Few copies of this first edition are known to be in existence; the editions of 1633 and 1636, enlarged by Thomas Johnson, apothecary (after the death of the author in 1607), being the ones most commonly met with in book-sales and in the possession of dealers. One of the 1633 edition, on large paper, is reported to have been sold, between two and three years since, in London for about $180.

The Dosage of Opium for Infants.—Dr. A. Walt, of Oakdale, Mass., writes us, enclosing the copy of a prescription for a child under two years of age. In a four-ounce mixture there were four drachms of laudanum, and the dose was a drachm, or nearly eight minims, every three hours. He asks if the druggist was right in making it up. We should say that the doctor was not right in writing it.

A Training-school at Willard Asylum.—This asylum, now the largest and best organized institution for the insane in the United States, has taken another step in advance by the organization of a school for the purpose of training the attendants to the intelligent performance of their duties. The course of instruction will extend to two years. There are now forty persons in the class. We congratulate the managers and the superintendent, Dr. P. M. Wise, on this new feature in their management.

New York State Medical Society.—Additional papers to be presented at the next meeting. Since the publication of the list of papers to be read at the coming meeting of the Medical Society of the State of New York, the following papers have been offered: "Embolism of the Radial Artery Complicating Endocarditis" (in abstract), by F. E. Martindale, M.D., of Port Richmond; "Modification of Chadwick's Gynecological Table" (model and photos), by Charles Stover, M.D., of Amsterdam; "Ametropic Condition of the Eye as a Factor in Cephalalgia," "Treatment of Small Perforations of the Membrana Tympani, with Reference to Formation of New Tissue," by B. H. Grove, M.D., of Buffalo; "New Nasal, Pharyngeal, and Laryngeal Instruments," by Samuel Sherwell, M.D., of Brooklyn; "Seven Cases of solid Pelvic Tumors successfully Removed by Laparotomy," by M. D. Mann, M.D., of Buffalo; "Observations on Diphtheria: Its Complications and Treatment," by E. N. Liell, M.D., of New York. The Society will be convened at 10 A.M. on Tuesday, in the City Hall in Albany.

We learn from Dr. S. B. Ward, of Albany Chairman of the Committee of Arrangements, that the Delaware & Hudson Canal Company's Railroad will sell return

tickets from the meeting of the Medical Society of the State for one-third of the usual fare, on a certificate issued by the Secretary at the meeting that the holder is entitled to the reduction.

A similar arrangement has been made with the New York Central & Hudson River Railroad to sell return tickets at half-fare; and it is altogether probable that the same arrangement will be made with the West Shore Railroad.

The Springfield Hospital, at Springfield, Mass., has lately received a bequest of $75,000 from the estate of the late William Merrick.

New Books.—There were 5,210 new books or new editions published in the United Kingdom in 1886. Of these 114 were new medical books, and 57 were new editions of medical works. Only 18 new books on law were published, while there were 616 upon theology.

Professor C. Westphal has recently celebrated the twenty-fifth year of the beginning of his career as a teacher in the University of Berlin. Professor Westphal was the successor of Griesinger, and to these two are due reforms in the treatment of the insane.

Cholera has appeared in Chili, South America.

The Medical Association of Canada will hold its next meeting, under the presidency of Dr. Graham, of Toronto, in Hamilton, Ontario, during the week following the meeting of the International Medical Congress in Washington.

Dangers of Antipyrine.—Dr. George D. Hays calls attention (*N. Y. Medical Journal*) to the dangers in the use of antipyrine when given in repeated doses. Very serious collapse has been observed in several cases.

A Signal Failure with Narceine in the treatment of whooping-cough is reported by Dr. L. Eliot, in the *Journal of the American Medical Association*. The dose used was gr. $\frac{1}{24}$, but it produced great drowsiness and entire suppression of urine. Perhaps the narceine was only impure opium.

Small-pox in New York.—Small-pox has appeared very suddenly and developed with much rapidity in this city. Up to January 11, 1887, there had been but 1 case reported during the winter. In the next week there were 25 cases reported, with 2 deaths. Up to Monday last there had been 32 cases reported, which is more than have occurred in the city since 1882, as shown by the following table:

Years.	Cases Reported.	Deaths.
1881	1,342	451
1882	708	259
1883	26	12
1884	5	..
1885	105	26
1886	109	31

The source of the present contagion seems to have been mainly in the neighborhood of West Fiftieth Street and Seventh Avenue. A few cases have been contracted on shipboard and brought through the quarantine before the disease had made itself known. Yet another source seems to have been the mysterious case of the Mauri family, in Brooklyn, to which it is thought a few of the earlier cases may be traced.

Dangers of Water Gas.—The experience of the people of Troy in the use of water-fuel gas, shows that, unless this gas is made odorous, so that its presence in the air can be ascertained by the sense of smell, its manufacture and delivery in a city may largely increase the death-rate. Water gas having no odor, and being very deadly, may be as fatal to a man who is awake as illuminating gas is to a man who is sleeping in a closed room. This gas is an excellent fuel, and it is cheap. In Troy it was made for nine cents a thousand and sold for fifty cents.

Kreatinine and the Reaction for Sugar.—Dr. George Johnson states that the substance in urine which reduces picric acid in the presence of potash is kreatinine. This kreatinine, which causes a reaction like that of glucose, may be removed by a simple method devised by the younger Johnson.

Diarrhœa and Antiseptics.—In an admirable paper upon the treatment of summer diarrhœa by antiseptics, read before the Academy of Medicine recently by Dr. L. Emmet Holt, it was claimed that the treatment by antiseptics was the most rational and effective method, and that salicylate of soda was the most efficient of this class of drugs. This is a *non sequitur*, however, since salicylate of soda is only very moderately antiseptic, being some fourteen hundred times weaker than corrosive sublimate. The conclusions apparently, therefore, are not in harmony with the argument, although their practical value is not diminished.

Rhigolene is a better agent for the production of anæsthesia, in many operations upon the nose, than cocaine, according to Dr. William C. Jarvis. Dr. Jarvis has recently reported (*Eastern Medical Journal*) the results of three years' experience with this agent.

Scopoline as a Substitute for Atropine.—Dr H. Percy Dunn writes, in the *British Medical Journal*, that the new mydriatic, scopoline, introduced by Pieral Thurey is a useful drug. For some time he has used scopoline at the West London Hospital, not for the purpose of testing its qualities as a mydriatic, but as a drug to supersede atropine in the treatment of keratitis, corneal ulcers, and iritis. He has found that, in the case of troublesome corneal ulcers which had been treated respectively with both atropine and eserine without success, rapid improvement followed the instillation of scopoline. Especially was this good effect shown in cases of severe interstitial keratitis, in which atropine had been previously employed. Again, in rheumatic iritis the use of scopoline was obviously effective in reducing the pain and injection of the globe. Upon no occasion has he seen any conjunctival or other irritation set up by its use, and he has found one grain to the ounce a sufficiently strong solution for all purposes.

Death of an Aged German Professor.—The death is announced of Professor Baumgärtner in the eighty-eighth year of his age. He was for a long time Director of the Medical Clinic at Freiburg.

The Flatbush Insane Asylum.—Dr. John A. Arnold, of Brooklyn, has been appointed medical superintendent of the Insane Asylum at Flatbush, of the Kings County Farm, and Kings County Hospital.

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, January 24, 1887.

LAURENCE JOHNSON, M.D., PRESIDENT, IN THE CHAIR.

DR. E. WAITZFELDER read a paper on

THE USE OF ACONITIA IN THE TREATMENT OF NERVOUS DISEASES,

in which, after speaking of the physiological action of the drug, he mentioned several affections that he had seen benefited by its administration. It had been, in his experience, especially useful in neuralgias of the trigeminus. Marked benefit may be derived from its use in the treatment of the pain of chronic pachymeningitis, whether syphilitic or not. In the fulgurating pains of locomotor ataxia it was not of any service. Some forms of insomnia could be benefited sometimes by the use of $\frac{1}{100}$ of a grain, especially when aided by bromides.

DR. WEBSTER mentioned a case of pachymeningitis in which he gave $\frac{1}{200}$ of a grain of the drug with benefit, when the pain yielded only partially to morphine. He referred to another case of severe headache in which no benefit attended its use.

DR. LESZYNSKY thought that the drug should be given in granules, so that the exact quantity administered might be known. In general, he thought that aconitia would not be a safe remedy to employ, and that it should be resorted to only after other drugs had been used without benefit. For he had seen very alarming symptoms produced by $\frac{1}{100}$ of a grain. In all affections attended by exhaustion, or liable to be, aconitia should be used with the greatest caution. He had used the oleate of aconitia prepared by Dr. Squibb, with benefit, as a local application in facial neuralgias.

DR. MESSENGER used aconitia externally, as far back as 1853 or 1854, and came to regard it as a dangerous remedy. It had, however, proved beneficial used as an ointment in syphilitic cases, especially when combined with veratria.

DR. O. B. DOUGLAS had given the tincture of aconite with very marked success in one case, and DR. WEBSTER also had used the tincture; but DR. WAITZFELDER said that he had confined his paper to the use of aconitia as a remedy which could be given in a more certain dosage than the tincture of aconite or the fluid extract. He quite agreed with Dr. Messenger and Dr. Leszynsky, that the drug was a dangerous one, and one not to be used when exhaustion was present or likely to be; still many other remedies were equally dangerous, but, with proper precaution, were at the same time very serviceable.

THE RELATIONS OF THE MEDICAL PROFESSION TO THE HEALTH DEPARTMENT,

was the title of a paper presented by DR. JOHN C. PETERS, in which he said that they must always be more or less disagreeable, because the laws of the State of New York forbade any physician from being president of the Board of Health. He urged that action be taken to ask the Legislature, the Governor, and the Mayor of the city to use their best endeavors to place a physician at the head of the Board of Health of this city.

The writer then referred to the case of Brown *vs.* Purdy, and he thought that the Society and Dr. Purdy had a just claim for exemplary money-damages against the Board of Health, and hoped that it would be pressed at the proper time.

Reference was also made to the requirement that the Board of Health notify families with contagious diseases about disinfecting, and which it almost invariably neglects, and did not send directions to physicians, who had to send for them and run a risk of being fined if they did not.

The Croton River and its tributaries abounded with nuisances, which the Board of Health had inspected in full detail, but had neglected to send an official report thereof to the State Board of Health and to the Department of Public Works; the State Board of Health could do nothing until officially informed by the City Board of Health. In the meantime

THE CROTON RIVER INCREASES IN NASTINESS.

The gallant Colonel of the Seventh Regiment, secretary of the Board, could not see the nuisances in the "Shanty Block," although it abutted directly on the grand armory of the Seventh Regiment. This might, by some, be regarded as a greater dereliction of duty than that of the General.

The Committee on Hygiene reported on

THE PROPER DISPOSAL OF MANURE.

The report contained an account of the complaints that were made concerning the manure-dumps, the manure-pits, etc., and the Committee concluded that the present manner of storing, removal, and disposal of the accumulation of stables in this city was done in a most slovenly and careless manner; that the manure-pit was a public nuisance, and a source of annoyance and disease to the neighborhood, and that the only way of properly doing away with this was to press the manure into bales. The process of baling is carried on at the model stables of Ryerson & Brown. The Committee had recommended to the Board of Health that the manure should be baled, so that it might be removed without offence, and do away with the disgusting manure-pit.

THE HEALTH COMMISSIONERS REPORTED

to the Committee on Hygiene that there was but one press in use in the city; that a machine costs $150; that at only one stable was manure being baled (Smith & Stills); that Ryerson & Brown had discontinued baling, and did not intend to resume; that Smith & Stills deliver their bales to Peter Donnelly's manure-dump, where he opens them, as there is no sale for baled manure; that their estimate was that sixty thousand horses were stabled within the city, etc. Michael Kane had found (Kane & Wright) baling manure at the stables to be utterly impracticable. Peter Donnelly stated that baled manure quickly heated in the bale, which rendered it useless for farming purposes; that after it was pressed it was almost valueless, as all its substance had been removed.

The question was discussed by DR. D. B. ST. JOHN ROOSA, who said that it was no concern whatever to the medical profession whether or not the baling of manure was a profitable business for Mr. Michael Kane and others, and that the Board of Health was open to criticism in presenting the subject from that point of view.

IS IT, OR IS IT NOT, A NUISANCE TO HAVE MANURE REMOVED AS IT IS NOW DONE?

was the question to be answered. He moved that the Medical Society of the County of New York request the Board of Health to abate the nuisance of the removal of manure as it is done at the present time in this city.

Until that question was settled, would the Board of Health have the kindness to have the manure removed, as is other offal, between the hours of twelve and three o'clock in the night?

DR. F. R. S. DRAKE seconded the motion in a few remarks, and the Society adopted it unanimously.

THE PRESIDENT AND THE BOARD OF HEALTH.

DR. JOHN T. NAGLE read from the last printed minutes the following quotation from the President's inaugural address (p. 47):

"The manner in which one particular bureau of the Health Department is conducted—that of vital statistics—is a matter of interest both to the profession and the

people. I presume there are few members of this Society who have not, at one time or another, been greatly annoyed, not to say injured in professional standing, by the return for correction of certificates of death upon the flimsiest pretext. No honest man doubts the necessity for rigid scrutiny of such certificates, but such scrutiny can be made without discourtesy, and trivial errors corrected without a degree of annoyance to both physician and friends that is as mischievous as if incited by malice."

He moved that this portion of the President's address be referred to the Committee on Ethics, with the request that the Committee investigate the statement, and report to the Society at an early date.

The Vice-President, Dr. Drake, was called to the chair.

The President seconded the motion, for the purpose of having an opportunity to discuss it, and the question was further discussed by Drs. Drake, Nagle, Fry, and Irwin, after which Dr. Nagle withdrew his motion, and moved that a committee of five be appointed by the Chair, to which the statement read should be referred for investigation and report to the Society as early as possible.

The Vice-President subsequently appointed as the committee Drs. D. Lewis (chairman), O. B. Douglas, J. S. Warren, W. M. McLaury, and J. W. Warner.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 20, 1887.

A. Jacobi, M.D., President, in the Chair.

THE VALUE OF QUININE AS AN ANTIPYRETIC IN PNEUMONIA.

Dr. John Ripley read a paper [see p. 113] on the above subject, and was followed by Dr. Mary Putnam-Jacobi, who gave an abstract of her paper on

THE USE OF QUININE IN THE PNEUMONIA OF CHILDREN,

read before the Section in Practice, January 18, 1887, the discussion being postponed until this meeting. The paper was based upon observations made in one hundred cases occurring in dispensary practice. Only 33 cases could be followed to their completion, but in an additional number, sufficient to make 53 in all, were fairly satisfactory observations recorded. The ages of the children varied from six months to four years, the average being about two and a half years. The doses were ten grains daily, five at night and five in the morning. There were 33 unquestionable recoveries, and 7 deaths, but the mortality was doubtless more than seven per cent. The modification in physical signs, to which special attention was directed, pertained to the blowing respiration and tubular breathing. These disappeared during the use of the quinine in from two to seven days in 29 cases; in from eleven to eighteen days in 7 cases; and in 1 case after three weeks. The fever disappeared entirely in 32 cases; on the second day in 8 cases; on the third and fourth day in 3 cases; on the fifth day in 5 cases, etc. In 25 cases, defervescence occurred within seven days from beginning the quinine; in 7 cases, later.

The writer concluded that in the pneumonia of children quinine in daily doses of ten grains does not act as an antipyretic, but that it causes defervescence or arrest, temporary at least, of the morbid process. A forced defervescence would be of but little advantage in broncho-pneumonia.

The author of the paper then discussed the pathology of pneumonia, and the effect which quinine has in producing an active diastole of the heart, thus explaining the tonic action of the drug on the circulation, although large doses will produce undue diastole. Quinine was indicated when there was no fever, but only consolidation was present.

The conclusion reached was that quinine was specially indicated to avert the tendency to death.

The discussion was opened by Dr. J. Lewis Smith, who said that a large majority of physicians in this city used quinine in the treatment of broncho-pneumonia, and it seemed to be the remedy most commonly employed in the treatment of pneumonia, whether catarrhal or croupous. His mode had been to give quinine for three or four days only, in what might be called large doses, and then continue it in small doses, with carbonate of ammonia between, and the rate of mortality had certainly been less than it was twenty-five years ago, when the more heroic and depressing measures were adopted. He had been excessively annoyed by the vomiting which had so frequently attended the administration of quinine, and while an emetic might not do any harm, and quinine might be as good an emetic as could be employed, still the drug was administered for other purposes, which rendered it desirable to have it retained. To obviate vomiting the best vehicle he had used was the syrup of the wild-cherry bark.

Dr. J. H. Fruitnight's experience had been similar to that of Dr. Ripley. He had never been convinced that quinine reduced the temperature in pneumonia, but he still continued to use it for its sustaining effect, and for this purpose only small doses were required.

Dr. F. A. Castle's experience bore out the statements made by Dr. Ripley concerning the uselessness of quinine in the treatment of pneumonia. He had carried its use to the full degree of toleration by the stomach, and it had seemed to him that it was at the expense of the patients' nutrition. During the last five years he had abandoned its use in pneumonia almost entirely. To sustain the heart he preferred digitalis to quinine.

Dr. C. E. Billington had found that the best method of administering quinine to children was by suppositories. He had taken occasion to study the natural history of pneumonia in children, and had reached the conclusion, based upon observations made in conjunction with Dr. A. A. Smith in twenty cases, that with a very simple treatment this class of patients would recover from it in most cases.

Dr. L. E. Holt had given quinine for its antipyretic effect in twenty cases of pneumonia in children. From sixteen to twenty grains were given to children from one to two and a half years of age. In twelve not much, if any, antipyretic effect was produced; in eight there was total failure. In two or three cases the temperature rose steadily while the quinine was being taken. He had stopped its use altogether during the last two years, because he regarded it as useless in small doses, and dangerous in large doses. Quinine, however, was of decided advantage in convalescence and in persistent broncho-pneumonia, and for its tonic effects.

The President referred to the changes that had occurred during the last third of a century in the profession concerning the use of quinine in pneumonia. At the beginning of that period it was customary to give from one-half to one grain of quinine a few times a day, with great expectations, and a large number of children got well. It was true that the tendency was toward recovery in many diseases occurring in children. And therefore it was only in the bad cases that the effect of remedies could be measured. At that time he gave from six to twelve grains of quinine daily, and made for himself the reputation of giving such doses as were liable to kill the patient. But times have changed, and while he seldom goes beyond the doses he then gave, many physicians had given twice or three times as much without endangering their reputations at all. Dr. Jacobi always gives the quinine during the remission of the fever, say five grains in the morning at eight o'clock, and five grains at eleven o'clock, to anticipate the afternoon exacerbation.

It had occurred to him that much of the inefficiency ascribed to quinine was not due so much to the drug as to the fact that the stomach was not in proper condition

to absorb it when taken; for the stomach with a temperature of 104° or 105° F. does not absorb, and the same was true of the rectum. When given subcutaneously it produced its effects rapidly, and the best solution for hypodermic use that he had used was that of the *carbamide* of quinine, which was readily soluble in quantities of four or five grains, in sufficient water to fill the barrel of an ordinary hypodermic syringe. It was not worth while to give quinine when the temperature was no higher than 102°, or 102.5°, or 103° F. He also believed that the large doses spoken of were detrimental. When pneumonia occurs that does not undergo resolution, with increased temperature in the afternoon and considerable cough, the patients will do well under quinine given in the forenoon.

Dr. Ripley said that in a large number of cases in which he used quinine hypodermatically, the result was the same as in the cases in which the drug was retained by the stomach. In none of the cases reported was the quinine vomited. In a large number of instances, it was true, as Dr. Jacobi had said, that the drug would not be absorbed.

With reference to long-continued pneumonia in children, he thought that pleurisy existed as a complication, which produced the prolongation of the disease, and he had found the same conditions in adults.

For hypodermic use he had employed the *muriate* of quinine, which could be dissolved in the proportion of forty grains to the ounce of water by the aid of heat. As the solution cools, crystallization takes place, but the fluid readily becomes clear when again warmed for use.

The President had used a saturated solution of the quinine by the aid of a slight quantity of acid, and had found that the fluid portion was absorbed and the quinine remained in the subcutaneous tissue. He therefore thought it not always desirable to make the solution for hypodermic use too concentrated.

Dr. John E. Weeks then described, and exhibited with microscopes, specimens of a small bacillus that he had observed as of constant occurrence in

ACUTE MUCO-PURULENT CONJUNCTIVITIS,

popularly known as "pink-eye."

The observations included about two hundred and fifty cases. Cultivations of the small bacillus were made with great difficulty, as the microbe would not grow on the ordinary food media. A perfectly pure cultivation was not obtained, but the contamination, a clubbed bacillus, was cultivated pure and experimented with. Inoculation of the conjunctiva of inferior animals and of man with the pure culture of the clubbed bacillus produced no inflammatory results. With the cultivation, which consisted of the small and the clubbed bacillus, the former largely predominating, inoculations of the human conjunctiva were performed, and in all the inoculated eyes the typical muco-purulent conjunctivitis was produced. The inflammation appeared about thirty-six hours after the inoculation in every case. Five days after the inoculation of one eye the other eye became affected.

Microscopical specimens of the small bacillus in the secretion from the conjunctiva, in and on pus-cells, in nearly pure culture with the contamination, and a pure culture of the clubbed variety, were shown. Cultivations in test-tubes of the above two varieties were shown, also cultivations of ten other varieties of microbes taken from the healthy and diseased conjunctiva, including the staphylococcus pyogenes, aureus, albus, and citreus, but not including the coccus of Neisser nor the trachomacoccus of Michel, were exhibited.

The cultivations were in gelatine and on agar-agar. Inoculations of each of the ten varieties, thoroughly tried on the human conjunctiva, failed to produce inflammation. He considered the *small bacillus* to be the cause of acute contagious conjunctivitis, the form mentioned.

The Academy then adjourned.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A CASE OF RECOVERY FROM TUBERCULAR MENINGITIS—ANATOMICAL TEACHING—A PRIVATE MEDICAL SCHOOL—THE SEVERE WEATHER AND DOCTORS—OUT-DOOR AND IN-DOOR PRACTICE—THE WILSON BEQUEST—THE NEW PRESIDENT OF THE PATHOLOGICAL SOCIETY—GUY'S HOSPITAL AND ITS DIFFICULTIES.

London, January 10, 1887.

Tubercular meningitis is generally considered as being almost invariably fatal, but at the last meeting of the Pathological Society Dr. Carrington read a case which goes far to upset this opinion. The patient was a boy, aged sixteen, with a good family history, who had been knocked down by a tricycle. The right knee was injured, and considerable swelling ensued, with impairment of movement. Fifteen months later the left knee began to be affected. He improved under treatment, but in January, 1886, he was admitted into Guy's Hospital for psoas abscess on the right side. In April he left the hospital considerably improved by treatment, but in October was readmitted with another abscess on the left side. He gradually became worse and died. At the post-mortem the pia mater and arachnoid were found thickened, granular, and matted together. On examining the membranes carefully, small, yellow caseous tubercles were found, and their tubercular nature was confirmed by microscopic examination. The brain was healthy; so was the cord, except that the latter was softened. There was meningitis at the lower third of the cord. At the apex of each lung were old phthisical lesions. Two of the lumbar vertebræ were carious, and the right knee-joint was completely disorganized. There was lardaceous disease of the spleen and small intestines, but the other viscera were healthy. Dr. Carrington said he was disposed to lay much stress upon the concomitance of old tubercular phthisis, old cerebral meningitis, caries of spine, and chronic joint disease as evidence of the nature of the meningitis. He believed that it was tubercular, and had been recovered from. The spinal meningitis was probably more recent, and due to the same cause.

The teaching of anatomy has undergone great changes since the days of John Hunter. Before the passing of the Anatomy Act bodies had to be surreptitiously obtained and, being scarce, preserved as long as possible so as to get as much instruction as possible from each. Preservative injections and antiseptic solutions wherewith to preserve the part were unknown. The sights and smells of dissecting-rooms in those days are therefore better imagined than described. Nowadays I have seen many a "part" kept perfectly fresh and sweet for two or three months by the aid of either methylated spirit or carbolized water, a cloth soaked in one of these being wrapped round the part, and the whole enclosed in Mackintosh cloth to prevent evaporation. Dissection is now confined to duly licensed places of study. In London each medical school possesses, of course, a dissecting-room, and a certain amount of dissection also goes on at the College of Surgeons, and some other of the examining bodies. Private dissecting-rooms have almost wholly disappeared, that conducted by Mr. Thomas Cooke being, I believe, the only one extant in the metropolis. Mr. Cooke, although an Englishman by birth, was educated at Paris, where he graduated in arts, science, and medicine. He was for a time Demonstrator of Anatomy at the *École Pratique* of the Faculty of Medicine. Proceeding then to this country,

he became a Fellow of the College of Surgeons of England by examination, and obtained the appointments of Assistant Surgeon at the Westminster Hospital, and Demonstrator of Anatomy in the Medical School. On ceasing to hold the latter post he founded the private medical school which he has since conducted for about fifteen years. Anatomical instruction formed the basis of the school, but physiology, histology, chemistry, materia medica, and operative surgery, are now taught, both theoretically and practically. Mr. Cooke has obtained suitable premises for the purpose in a central part of London, and that part of his teaching which comprises instruction on the dead body is carried on in two iron buildings erected on an isolated piece of ground at a distance from any dwelling-house, and consequently no nuisance is caused. Many students have to thank Mr. Cooke for a large measure of their examinational success, and his persevering efforts have just obtained for him from both the College of Physicians and the College of Surgeons the recognition of his school as a place of medical study in the case of those candidates who, rejected at their first examinations, have to produce certificates of further study. These certificates can now be given by Mr. Cooke. Although his teaching absorbs a large proportion of his time Mr. Cooke also practises, but, practising solely as a consulting surgeon, he does not use his "M.D. Paris," but his name appears on his door-plate with the simple prefix of "Mr."

The late severe weather has been very unfavorable to doctors. As a rule here, the doctors go to their patients —not the patients to the doctors, even when well enough to do so. I am speaking of general practitioners, who constitute the great majority of the profession. To consultants patients frequently pay a visit instead of summoning them to see them, the reason being that, after the first interview, the fee for a home consultation is only one guinea, but two guineas for a visit. Consultants, though, have a certain amount of out-of-door work ; an afternoon round being a usual thing among those in good practice. But the latter can keep a carriage, and in this way with a good pair of horses a considerable distance can be rapidly and comfortably traversed over the smooth wood paving now laid down in the leading thoroughfares of London. The unfortunate general practitioner, though, has to make at least two rounds a day, if in large practice, and cannot always, in the poorer districts of London, afford to keep a carriage. As a consequence, he is always out—a fact of which many of his patients complain. A lady residing in one of the most fashionable western suburbs of London remarked to me a few days since that in her district none of the doctors were ever at home when sent for to an urgent case, and said she really thought it would pay a medical man to settle in the district and announce that he would remain at home all day to see patients, and not make a round out. Then, she said, you could always rely on finding one doctor in an emergency. I made the natural rejoinder that to a second patient sending he would be "out." On the other hand, if a suburban practitioner refused to visit at all he would soon find his practice melt away.

Apprehensions are rife that the Wilson bequest to the College of Surgeons may not be wisely used. It is feared that the Council contemplate putting a large sum of it in bricks and mortar, and that in addition a considerable amount of income now derived from ground-rents on houses contiguous to the college may be sacrificed by taking up all the available space for the purposes of the new buildings. The legacy is estimated to produce $1,000,000, but if not cautiously guarded even this large sum may be frittered away in unprofitable undertakings.

Sir James Paget is the newly elected President of the Pathological Society, and may be trusted to maintain the high reputation for honest scientific work that society has hitherto enjoyed.

Scarcely one-third of the $500,000 needed by Guy's Hospital has yet been subscribed.

LONG BEARDS, "SANITAS," AND HIS COAT-TAILS.

To the Editor of the Medical Record.

Sir: "Sanitas" pictures the method of catching diphtheria, or the contagion, by bringing the whiskers, rather than coat-tails, near the patient's face when making a professional examination ; and also says most doctors expose their faces by this manœuvre rather than their coat-tails ; but some may have idiosyncrasies which may destroy his argument. This is really very cunning, but let us see how it will work if applied to other cases. Diphtheria is not the only disease, nor is examining a patient the only method of getting a load of contagion which may be conveyed by the doctor. I have mentioned that contagions material may be deposited upon door-latches, car-seats, privy-seats, church pews, drinking-utensils, cash, clothing, or most any other substance. Now, I do not know what are the idiosyncrasies of some folks, but out West a man is not so likely to get contagion in his whiskers from car-seats, privy-seats, etc., as he is in his coat-tails. Verily, if "Sanitas" cuts off his whiskers as a measure of sanitary engineering, he must, if he carries out his good intentions, be found standing on his head in many places to save his coat-tails.

I will continue my argument in the words of "Sanitas," merely substituting "coat-tails" for "beards." "The plain facts appear to be this [he should have said these] : The customs of society, and precedents in our profession have decreed that long coat-tails are not suitable for those who attend the sick. The coat-tails carry contagion, and are particularly adapted for the lodgement of germs. Let the physician at least reduce the risks of this kind as much as possible."

To conclude, there are many men, East and West, who wear no whiskers and roundabouts. "Sanitas" can't be distinguished by this dress through his assumed name. Forty thousand doctors, more or less, want to know who "Sanitas" is. He has only to hitch his name to his glory and wake up to fame. Come, "Sanitas!" give us your name, who made you, what county you live in, and we will give you a rest. Romaine J. Curtiss, M.D.

DANGER IN TOAST.

To the Editor of The Medical Record.

Sir: A Russian author in a recent novel makes all his principal characters devils. Satan, as chief, directs the lesser devils each to his separate task, which is to corrupt mankind, and to bring sorrow and woe where there had been happiness and rejoicing. With what success the story tells.

If we can conceive of disease as some archfiend, bent upon bringing pain and suffering and helplessness and death to the whole human family, using as his emissaries broods of bacteria, each seeking and finding their own organs to attack, we have here materials for a tragedy equalling in interest Tolstoi's weird tale.

But the foes of health are not all included in the various forms of cocci. There are many other causes of disease that work with charming regularity, and all the more so because they are entirely unsuspected. One of these is toasted bread. An innocent-looking thing, and yet, like the Grecian horse before the walls of Troy, it works sad havoc when once inside.

It is with some hesitancy that I venture to say anything against toasted bread, for did not our mothers and our grandmothers and our great-grandmothers always give it in sickness, and does it not even now hold a sacred place in the heart of every housewife? Surely an idol-breaker is not to be envied, and yet I cannot forbear giving a few plain facts from my own experience tending to show that there are times and circumstances under which it seems to do great harm.

Years ago, a room-mate in college was taken with ty-

phoid fever. He passed safely through the disease and was considered convalescent, when near the fourth week his physician permitted him to eat a piece of toasted bread softened in milk. Three hours later he grew worse, had a relapse, and died in a few days.

Some time ago I was called away from my practice, at a time when I had two typhoid-fever patients in charge—one convalescent, the other in the third week. I cautioned the families not to give them toast as they grew better, but as soon as the morning temperatures became normal it was given, resulting in a relapse, though not a fatal one, in each case.

Last summer several dysentery cases suffered relapses in the same way from eating toast.

One illustration will suffice: Mrs. B——, a delightful lady, was taken very severely with this trouble. Large enemata, and hydrarg. bichlor., gr. $\frac{1}{100}$, every two hours brought speedy relief. A diet list was carefully made out and a special and emphatic warning left against toast. But with a perversity of appetite which others may be able to explain, toast was the one and only article of food which she wanted. A liberal bill of fare had no attractions for her; toast alone would satisfy her craving, and toast she ate. (Who is prepared, in the light of this incident, to say that the story of Eve and the apple is a myth?) An hour or two after indulging she was taken with violent pains (I refer to Mrs. B——, not to Eve) and all her symptoms returned in an aggravated form. She was a very penitent and tractable patient during the rest of her illness and has permanently abandoned the use of toast in sickness. I had five other cases, where, after the pain and discharges had ceased, they were brought on again by the use of toast. I have seen it produce pain and vomiting in gastric catarrh, in fibroid induration of the stomach, or whenever there is inflammation of the mucous membrane of the gastro-intestinal tract. In inflammatory diarrhœas of children the anxious mothers are forever giving toast, and it in turn is forever giving pain and more diarrhœa. It would seem as if the gritty particles of charcoal, insoluble in the juices of the stomach, are shoved up and down over the irritable mucous membrane like so much powdered glass, and finding their way into the intestine scratch the inflamed Peyer's patches, or the angry mucous membrane, as the case may be, renewing and aggravating inflammatory action.

We are taught to beware of the danger that is dissolved in our drinking-water, of the germs that lurk in the air, of the mince-pies that linger in our stomachs; ought we not in inflammatory conditions of the stomach and bowels, enforce a strict quarantine against the "pernicious activity" of toast?

E. W. HEDGES, M.D.

PLAINFIELD, N. J.

"REPORT OF A CASE OF TYPHOID FEVER IN WHICH ANTIFEBRIN WAS USED SUCCESSFULLY AS AN ANTIPYRETIC AGENT."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Such are the head-lines of an article in the MEDICAL RECORD, January 1, 1887, by George R. Elliott, M.D.

You will please pardon a few questions from an old physician of a sceptical turn of mind, who desires to know something more in regard to the treatment of this essential fever in New York.

The new antipyretic "was used successfully," but the patient died on the twenty-first day of the fever, notwithstanding. How much the treatment and how much the essential poison contributed to the death of the unfortunate young man may never be satisfactorily measured. But the diagram of fever range, and history of treatment, form a reasonable pointer to a rational conclusion, and forcibly remind the reader of experiments by way of advertisement of a new remedy.

Dr. Elliott saw the case at the close of the first week, and in forty-eight hours after this the patient had taken calomel and eighty grains of quinine, the latter in doses of fifteen and twenty grains, and would have received more but for the induced heart-failure and dyspnœa. Under this treatment "the stools were frequent," with tympanites, delirium, and subsultus, with a temperature of $104\frac{3}{5}°$, which continued throughout the second week without variation or remission. Now, at the end of the second week, the doctor calls in the "new remedy," and says: "It was evident that unless the temperature could be controlled, the prognosis was rendered correspondingly more grave." Is "temperature" the synonym for the disease? Large doses of quinine had been given, but not to reduce the temperature. Eighty grains were given to "*exclude a possible malarial element.*" "The further use of quinine was abandoned, for, in our experience as an antipyretic agent in typhoid fever, it is useless. I have repeatedly employed it in a large number of cases of typhoid fever in hospital practice, with the *prime object in view* of testing its efficacy as an antipyretic agent, and can *positively state that in no single instance have I ever seen it reduce temperature. In all cases when it did so act*, an unmistakable malarial element has been *proven to exist*" (italics my own). The temperature under large doses of quinine remained the same, and the doctor was satisfied he "*had excluded a possible malarial element and was dealing with an unquestionable case of typhoid fever*," and by means of "antifebrin" kept the temperature below 103°. Still, in this case of typhoid fever, with the "malarial element excluded," and the temperature or disease doing wonderfully well, the doctor seems to have been unhappy, and "*resolved again to try quinine in large doses, and gave fifteen grains*, repeating in four hours." We are told this was done to "*exclude a possible coincidence.*"

But why try quinine again in large doses, when its effects on a case of typhoid fever, with the "possible malarial element excluded," were so positively known to the prescriber? It had been used to expel one possible phantom—why use it at this late and most dangerous juncture to expel another? We are not told that the young man had voluntarily sacrificed himself to the wiles of science; but had he done so, the experiments were as unjustifiable as they were disastrous. It would be natural to suppose caution would be exercised by one who had so frequently employed quinine, in such a large number of cases of typhoid fever, with the prime object in view of testing its efficacy as an antipyretic agent, and who positively never found a single instance—no, not one, where it reduced temperature—still, where it did reduce the temperature in typhoid fever, an unmistakable malarial element has been proven to exist. In early days, or times past, it was not considered true science to prescribe for some prominent symptom of a disease and give no attention to pathological conditions of the suffering organs. It has been said, "Nature is fighting disease," but the physician should not represent the blind man with a club striking at random—he may kill Nature in his vain attempts to aid her.

Does anyone know that antipyretics have diminished the mortality of typhoid fever? Does anyone know it is the temperature that destroys the patient? Is not the ratio of mortality in this fever much greater where the temperature-point is little changed from normal?

Does anyone suppose a rise of the temperature-point necessarily implies an increase of the production of heat? Does anyone know that the rise of the temperature-point is not a conservatory provision of nature? If not, why should the afflicted father agree with the attendants, that the antifebrin effects were simply wonderful, and volunteer the statement that "*no possible relationship could be established between its use and the fatal result?*"

N. E. JONES, M.D.

CIRCLEVILLE, O.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 16 to January 22, 1887.

FORWOOD, W. H., Major and Surgeon. Ordered for duty at Fort Meade, Dak. Terr. S. O. 5, Department of Dakota, January 14, 1887.

BROOKE, JOHN, Major and Surgeon. Ordered for duty as Post-Surgeon at Fortress Monroe, Va. S. O. 10, Division of the Atlantic, January 14, 1887.

GARDNER, W. H., Major and Surgeon. Ordered for duty as Post-Surgeon at Fort McHenry, Md. S. O. 10, Division of the Atlantic, January 14, 1887.

POPE, B. F., Major and Surgeon. Ordered for duty at Fort Clark, Tex. S. O. 15, A. G. O., January 19, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 22, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	4
Scarlet fever	49	10
Cerebro-spinal meningitis	6	5
Measles	651	68
Diphtheria	128	49
Small-pox	18	2
Yellow fever	0	0

HOW TO WRITE A PAPER FOR A MEDICAL SOCIETY.—In an address read before the Stark County, O., Medical Society, Dr. A. W. Ridenour, of Massillon, says many things that will doubtless interest a number of our readers: "The honorable president of this society wrote me a postal card, a short time since, saying that I was to prepare a paper for this meeting. No subject was mentioned, and none has been sent me since, although I have been anxiously waiting, and while waiting thinking what should constitute a paper. One person may consider it necessary to write a long dissertation on some abstruse medical problem in mycology, that he knew but little—*very little—about really*, and his listeners still less. During the reading of this paper *one* would be thinking of his patients, another of his deaths, another of his creditors, others of how badly they were used by their brother practitioners, and the balance staring at vacancy. To avoid this, we would require to make our paper *brief* and practical. We might take up the subject of fractures, and after telling you some things you already know, proceed to tell you things you did not know, and did not believe the writer knew either. One doctor would treat all fractures of the long bones with wooden splints, without weights and pulleys; another would use weights and pulleys, without wooden, or, in fact, any splints; another would suspend the limb in mid-air; another would use the Bavarian method with plaster; another would use the plaster *roller*, and so on—each believing his own method the best, and standing ready at any time to testify against all other methods; even for a consideration would swear that shortening was the rule, if his cases presented shortening, and, per contra, should he succeed in getting no shortening in one or two cases, even forgetting those of his cases where shortening was present. We might write about the great honor it was to be called a surgeon by the profession, a butcher by the people, and a murderer by the victims. We might say that the ancestors of the surgeons were barbers; and it might seem suggestive, in view of the great desire to lop off all tonsils of more than four lines in diameter. But it would not be right, in view of the actual condition of affairs, to say that it is not considered an honor any more by the people to be a surgeon, or rather an aspirant thereto. It would not be right to discourage the *gentle* rivalry that exists among nine out of ten of all practitioners, of all ages, condition, and sex, by saying that the more successful they become as surgeons the more they are shunned by the people. But we might say that some—perhaps the greater number of these aspirants after these *false* honors—want to pose before the eyes of their patrons as general practitioners, and not surgeons, always naming and designating some one else as being the surgeon, or, more properly speaking, in view of public opinion, 'The Butcher,' thereby getting the spoils, while the unfortunate *surgeon really* takes the *odium* attached to the name, and nothing more. It might be proper, then, to write a paper advising all thoughtful doctors to practise what they preach, and, *to be fair*, to let the spoils go with the odium; that it is perhaps true that a surgeon cannot live with less than a population of ten thousand, while a physician can live and save money in a population of one thousand; that it is preferable to be a general practitioner; that it seems incomprehensible how doctors will fight for the honor (empty) of being called a butcher by the people. It is true that doctors will almost tear each other's clothes off, so great is this rivalry, to aspire to be a descendant of the *Tonsorial Homo*. How much better it is to dandle the babies, talk about the weather, gossip, be a children's and a ladies' man, with a good *fat* family practice, have plenty of money, and no enemies, no suits for malpractice staring you in the face, and not be liable to the appellation of murderer. The grave will kindly cover the mistakes of the physician, while a crooked limb meets the aspirant to surgical dishonors at every corner. We might say this picture is overdrawn, and while it would be true as regards some, yet not true as regards the majority. But suppose we conclude to enlarge the scope of the paper, and embrace medical politics, general politics, theology, history, and *earthquakes*. If we enter the field of medical politics, we will allow our hair and beard to grow short quickly, avoid every thing that favors the development of positive electricity. Long hair and whiskers suggest combativeness, and, gentle listener, did you never pause to notice that long-haired men, *races*, *women*, and communities were very combative when crossed. Let us not carry this too far, however, lest we get lost. Inquire into the present controversy concerning the International Medical Exposition, and you will find exposed to view long-haired gentry arrayed on one side, and the short on the other This being the exact ground of controversy, it necessarily ends the subject of medical politics, and, as the length of hair forms a prominent feature in general history, we will devote a brief time to a discussion of that mighty subject. The Romans were finally conquered by short-cropped gentry from the north. The Indians were conquered by the short-crop; except recently when the aborigines began using the tonsorial appliances incident to the surgeon, since which time one Indian can manage a regiment of short-crops. The old Puritanical Cromwell cut off the hair of Charles I., and thus made a better man of him. Charlotte Corday cropped the hair of that fiend Marat, and civilization cheered. The long-haired Inquisition was finally abolished by short-bearded Protestantism, and so on. The short-bearded rulers of the old countries were always liberal with medicine, and never to enemies. Now we might say that the length of the hair and beard applies with equal force to the discussion of theology; we might say that liberal ideas go hand in hand with the short growth of the hair and beard. But while we are searching for a subject to write a paper on, we find that we are occupying more than a brief time, and hence we must hurry

along. What is an earthquake? We have various definitions to choose from, but we might say, without being accused of egotism, that an earthquake is an attempt of a portion of the earth's surface to stand on its head, while the remainder growls out its disapproval, the quake being the sensation of fear at the consequence of the act of balancing, if the attempt were successful; hence the trembling. Now having exhausted all the subjects under contemplation, it yet remains to ask, what shall we write about?"

The Performances of a Kansas Quack.—A correspondent living in Leavenworth, Kan., sends us the evidence given before a coroner's jury of a local quack who had been treating the deceased. The quack in question has no diploma, and relies in his practice, as we are told, mainly upon a certain salve. The following evidence tells the story:

"Maria Johnson, being sworn, says: 'I lived here with the deceased and others. She complained, about one o'clock on the night of the 23d inst., of cramps all over her body. I gave her red-pepper tea. It had no effect on her. When morning came I went for Dr. Fowler, and he came at ten o'clock. The deceased was still in pain. He then gave her the half of a dose of morphine he had in a spoon of water, and *in ten minutes* he gave her the other half. Then she went to sleep, and soon waking she complained of an itching and a hurting in her face; she then fell asleep, and we awoke her once. She opened her eyes and went to sleep again, and died at half-past eight last evening; she was subject to inward pains, and suffered in her limbs from rheumatism. Her breathing was hard and rapid before she died. Maria Johnson.'

"George Fowler, being sworn, states: 'I am a practising physician, and was called on the 24th of this month to see and prescribe for a girl named Carrie Carter, corner of Dacotah and Third in this city. On my arrival I found her suffering from a severe attack of bilious colic. I gave her *five grains of morphine* in two doses, half an hour intervening between the two doses. In my judgment, from the symptoms she manifested, she was *struck with death* when I arrived—her under jaw falling down and her eyes rolling back, leaving nothing but the whites to be seen. Her *pulse had moved up toward her elbow*, which in my opinion is a strong indication of approaching death. I observed the first dose of morphine had no effect in allaying the pain, and in fifteen minutes after taking the second dose she gradually got into a state of stupor. I then made an examination externally of her abdomen, and found small lumps over the surface of her bowels, and to the best of my opinion the pain and spasms accrued from these lumps. I then left the house, but returned between two and three o'clock, and found her sleeping, breathing very hard. Next morning I again called, and she was dead. I *do not think five grains of morphine was too much when divided into two parts, half an hour intervening between the doses.* Some time ago I gave her sister, Mrs. Richardson, *six grains of morphine*, and it had the effect of only making her drowsy.'

"Attest: George Fowler.

"John C. Lynch, Coroner.

"I generally buy my medicine at Aller's drug-store, and *use very little* of it."

Luther and Ménière's Disease.—Luther, when he was twenty-seven years old, was troubled with giddiness and sounds in his ears, and, as he was entirely ignorant of all physical science, attributed them to the devil. He says: "This toothache and earache I am always suffering from are worse than the plague. I am tormented with a noise and buzzing in my ear, just as though there is some wind tearing through my head. The devil has something to do with it. You don't know what a horrid thing this vertigo of mine is. Here all day I have not been able to read a letter through or even two or three lines of the Psalms. I have not got beyond more than three or four words, when buzz, buzz, the noise begins again, and often I am very near falling off my chair." This was in 1510. In 1530, he writes: "When I try to work my head becomes filled with all sorts of whizzing, buzzing, thundering noises, and if I do not leave off on the instant I should faint away. For the last three days I have not been able to look at even a letter. I have had another visit from the devil. My malady is made up of the ordinary weakness of old age, the results of habitual tension of thought, and above all by the blows of Satan. No medicine in the world will cure them or me." These noises in his head and ears were so confusing that in 1521, when some one gave him a bag of nuts which he put in a box in his bed-room, he thought the devil came and rattled them. He says: "When I put out the lights and got into bed, it seemed to me all at once that the nuts had put themselves in motion, not only jumping about in the sack, but knocking violently against each other, and then they came to the side of my bed to make noises at me. However, this did not alarm me, and I went to sleep; but by and by I was awakened by a great noise on the stairs, as though someone was tumbling down one hundred barrels, one after another. I rose immediately, saying: 'Is it thou, devil? Well, be it so, I commend myself to God.' I returned to bed and went to sleep. Again at Wittemberg I distinctly heard the devil making a noise; he thrice made a noise behind the store, just as if he were dragging some heavy thing over the floor. As I found he was going to keep it up, I gathered together my books and got into bed. At another time I heard him walking about, but, as I knew it was the devil, I paid no attention to him and went to sleep." Once when there was a great storm abroad, Luther said: "It is the devil who does this. Hark! how the devil is puffing and blowing." Then again he thought: "Idiots, the lame, blind, dumb are persons in whom the devil had established himself. All the physicians who try to heal these infirmities, as though they proceeded from natural causes, are ignorant blockheads. They know nothing about the devil or his works."

The Filiform Bougie.—A correspondent of the *Atlantic Medical and Surgical Journal*, writing from New York, says: "The most simple application of common sense is in the little instrument known as Banks' filiform bougie. We all can recall times when we have worried for days, trying to dilate an old, inveterate stricture, when we have taxed our ingenuity and the patient's patience, trying all the means at our command, and making but little satisfactory progress. I well recall one case in which it took me three days to get down three ordinary filiform bougies, putting in one and leaving it fifteen or twenty hours, and then passing another down beside it, and so on till I could get in a small steel sound, and thus I was three weeks accomplishing what I could now accomplish, with Banks' filiform, in thirty minutes. Banks' filiform and cocaine now are masters of the situation in most strictures. The only surprising thing about these filiforms is that we didn't think of the same thing a hundred years ago."

The Archæology of Artificial Limbs.—The history of medicine is all but silent on orthopædic surgery. And yet the Greeks and Romans, who, as archæology has shown, had anticipated much of modern dentistry, cannot have been without artificial substitutes tor limbs lost in the vicissitudes of peace or war. Herodotus tells us of a captive who amputated his foot to free himself from the shackle, and thus escaped to his friends, who replaced the limb by a wooden one. The Elder Pliny (Nat. Hist., vii., 28, ed. Mayhoff) records the case of M. Sergius, great-grandfather of Catiline, who lost his right hand in his second campaign, was wounded twenty-three times in two campaigns, and thus had the complete use of neither hand nor foot. Twice made prisoner by Hannibal, he twice escaped, after twenty months spent in chains. He fought four battles with his left hand

only, and then made himself a hand of iron, which he fastened on to fight with, and, thus accoutred, raised the siege of Cremona, protected Placentia, and took twelve camps of the enemy in Gaul. Similar substitutes for amputated arms or legs must have been in use even before the time of Sergius; so at least we may infer from the treasure-trove turned up at Capua, in 1885, in a tufa-grave. Among the contents of this tomb was an artificial leg, made of bronze, wood, and iron, the skeleton being entire, save the bones represented by the artificial limb. This (probably unique) relic is now in the Museum of the Royal College of Surgeons of London, and is thus officially described: "Roman artificial leg. The artificial limb accurately represents the form of the leg. It is made with pieces of thin bronze, fastened by bronze nails to a wooden core. Two iron bars, having holes at their free ends, are attached to the upper extremity of the bronze. A quadrilateral piece of iron, found near the position of the foot, is thought to have given strength to it. There was no trace of the foot, and the wooden core had nearly all crumbled away. The skeleton had its waist surrounded by a belt of sheet bronze, edged with small rivets, probably used to fasten a leather lining. Three painted vases (red figures on a black ground) lay at the feet of the skeleton. The vases belonged to a rather advanced period of the decline in art (about 300 B.C.)." Commenting on the above, General H. H. Maxwell says: "It is important to add, from other sources, that the upper third of the leg was hollow, while the lower two-thirds were filled with wood."

The Peculiarity of Malarial Disease in China, according to the Hospital Report of the American Episcopal Mission, is that there is a remarkable predominance of the quartan type, and the paroxysms are most likely to come on at night or in the afternoon.

The Mortality from Labor in China is estimated to be eight per cent., or about four hundred thousand deaths annually.

Small-pox and Measles in China.—Small-pox is spread every winter by the custom of inoculation. This is done by putting the variolous matter on a rag and inserting it up one nostril. No care is taken to isolate patients suffering from this disease. Measles are very common, and it is a well-known fact that one attack of measles here is no protection from the disease at home.—*Report of Hospital for Chinese, Shanghai.*

Gonorrhœa and Strictures. — Gonorrhœa affects the white and colored races with equal readiness, but the colored race is less liable to have strictures follow, according to Drs. McIntosh and Carter (*N. Y. Medical Journal*). Among whites there is about one stricture to four to ten cases of gonorrhœa; among negroes the ratio is about one to twelve to twenty-three cases.

Pelvic Hæmatocele.—Dr. Lawson Tait believes that there is no justification for any confusion about this disease. In the Ingleby lecture, recently delivered by him at Queen's College, in Birmingham, he endeavors to clear matters, and finally arrives at the following conclusions (*The Lancet*, October 30, 1886): That in the great majority of cases of extraperitoneal hæmatocele the disease may be left alone, being rarely fatal, and that it is to be interfered with only when suppuration has occurred. That, on the contrary, intraperitoneal hæmatocele is fatal with such almost uniform certainty that so soon as it is suspected the abdomen must be opened and the hemorrhage arrested. In the overwhelming majority of cases the source of the hæmatocele will be found in the broad ligament, and then it can be dealt with, and with every prospect of success. If anyone objects to this, he appeals again to the canon of surgery, which is of uniform application. For surgical hemorrhage, cut down and tie the bleeding point; if a big branch of the femoral artery were bleeding, my colleagues who deal in such cases would cut down and tie it. "Why should Poupart's ligament be a line of demarcation within which this surgical writ will not run? Why should my friend Dr. —— be allowed to do to the external iliac artery what I am prohibited from doing to the internal iliac division?"

Constipation.—Dr. A. V. Meigs, of Philadelphia, recommends the following combination of well-known drugs, in pill form, for the cure of obstinate constipation: ℞ Ext. belladonnæ, gr. $\frac{1}{2}$; ext. nucis vom., gr. $\frac{1}{4}$; aloes, gr. $\frac{1}{8}$; Rhei, gr. $\frac{1}{4}$—to be taken three times a day. ℞ Ext. belladonnæ, gr. $\frac{1}{12}$; ext. nucis vom., gr. $\frac{1}{4}$; ext. colocynth comp., grs. ij.—to be taken three times a day.

Malarial Hæmoglobinuria.—Dr. H. McHatton, of Macon, Ga., has made a study of this subject, and concludes therefrom, first, that this disease is purely malarial; second, that the jaundice is not dependent on impairment of the hepatic functions, but on the coloring matters of the blood following the disintegration of the red blood-corpuscles; third, that quinine is the only medicine which has any controlling influence on the course of the disease.

Contagious Pneumonia.—In the *Canadian Practitioner*, November, 1886, Dr. J. E. Graham describes a series of cases of pneumonia which he has recently observed. From a study of these cases, as well as the literature of the subject, he is led to draw the following conclusions: 1. That lobar pneumonia is in almost if not in all cases an essential fever. 2. That it is a parasitic disease. 3. That it frequently occurs in the form of epidemics. 4. That it occasionally has appeared to be contagious. 5. That the disease, in an epidemic or contagious form, is nearly allied to erysipelas. 6. That the early and persistent administration of tincture of iron is the proper treatment for these cases.

A Tonsil-knife.—Dr. G. W. Squires, of East Avon N. Y., describes an instrument which he devised, and has employed for some time, to scarify, or incise, the tonsils, which, he claims, possesses many advantages over the ordinary scalpel wound with adhesive plaster. It consists of a rounded blade, attached, longitudinally, to the side of a steel shaft, near its tip. A flat spring, of soft temper, conceals the blade from view, but by simple pressure the latter may be made to advance as far as desired, through a longitudinal slot in the spring. The mouth is opened, and the tongue depressed with a spatula. The instrument is then introduced, and the spring is made to rest against the tonsil. Then, by graduated pressure, the blade is protruded, and the tonsil is incised to any desired depth, without danger of wounding the carotid artery or any of the deeper structures.

The Advantage of Combining Antiseptic Substances.—Dr. R. Lépine writes, in the *Revue de Médecine*, No. 10, 1886, concerning some experiments made by him with mixtures of different antiseptic substances. He combined mercuric chloride, salicylic acid, carbolic acid, benzoic acid, calcium chloride, bromine, hydrobromate of quinine, and chloroform, each in very minute quantity, so that if it was alone in the solution it would be powerless to prevent the development of the bacillus subtilis in beef-broth. The solution as made, however, when mixed with an equal amount of bouillon, effectually prevented any development of this bacillus. The author believes that, by mixing different substances in this way, very powerful antiseptic solutions may be made, which will, at the same time, be entirely devoid of danger to the human organism.

Lady Visitor: "Well, how are you this morning, my dear?" Invalid: "Oh, very low indeed." "Have you seen a physician?" "Yes." "What did he say?" "That the malady was mortal." "And who is this doctor?" "It is Dr. X." "Ah, well, he was right; with him all maladies are mortal."

Original Lectures.

MULTIPLE NEURITIS AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.[1]

BY M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF NERVOUS DISEASES, NEW YORK POLYCLINIC.

LECTURE I.

MR. PRESIDENT, LADIES AND GENTLEMEN OF THE PATHOLOGICAL SOCIETY:

In inaugurating the course of lectures which bears the name of the founder, it is becoming that some expression of gratitude should be made to Dr. Middleton Goldsmith. This can hardly be associated with any form of personal encomium, since that would be as distasteful to him as it is needless before this Society, which owes its existence in part to his exertion. It is proper, however, to emphasize our appreciation of the motives which have led to the establishment of this lectureship. Every one knows that in the rapid progress of medical science, in the great and needful division of labor which that progress has made imperative, there is offered to each individual worker a vast mass of facts which cannot be easily grasped or even readily comprehended. To classify these facts, to weigh their importance, to draw logical conclusions from them, and to present these conclusions in a clear and accessible form is a work of no little magnitude, but of absolute necessity. To accomplish this specialists are at work in every department, and it may be well to emphasize the fact that it is the necessity for their labor, rather than any temporary fashion, that has led to that specialization in medical science which is so often harshly criticised. But special studies lose half their value if they are not made generally available. And it is just here that a lectureship such as this has its use. It enables the results of individual labor to reach beyond the specialist, to be placed before the general practitioner in a simple but comprehensive way. There is, therefore, no means by which an individual can make his influence more widely and permanently felt than by the endowment of such a foundation. For when his personal activity has of necessity ceased with the natural termination of an honorable career he may be sure that, yearly, facts and results are proclaimed in his name of immeasurable service to his successors and of benefit to the profession.

And now, before proceeding to the subject which is to occupy our attention for a time, let me express my obligation for the honor which this Society has conferred in inviting me to inaugurate this course of lectures. It is an honor to which I have no claim, and the duty incurred is one which I feel incapable of performing satisfactorily. I must beg your indulgence in the performance of the task you have laid upon me, and if I succeed in eliciting your interest I know that it will be because the subject we are to study together has a novelty which may compensate for the defects of its presentation.

The discovery of a new disease is never made suddenly. It is a gradual process, and certain stages in the progress toward its complete recognition may be observed. There is first the period of clinical observation, when isolated cases of an unfamiliar and mysterious affection are recorded as curiosities. To this succeeds the period of diagnosis, when, by a comparison of the now numerous cases, a clinical picture of the disease is gradually filled out. In this stage there is much to impede the progress of discovery. For not content with an analysis of symptoms, and a grouping of cases, the majority of observers offer theoretical explanations of the nature of the new affection, and an element of speculation enters which often obscures the facts. There is, however, a real progress in this period, for it is characterized by inductive reasoning from fixed data, and as a result reliable conclusions are reached which make a diagnosis possible. The third period is that of pathological discovery, when the morbid changes lying at the basis of the disease are accurately ascertained. In this stage erroneous theories are eliminated, true explanations for various symptoms become self-evident, and the exact nature of the affection is determined. The disease has now a status of its own. And at first this might seem to be the final stage in the progress of discovery. But it is not. There remains a period of etiological classification, when conditions, formerly supposed to be dissimilar are found to have a common basis, when the pathological changes are ascertained to be the same although the clinical pictures have varied, and when classification of the various forms is rendered possible and a definition of the disease is reached.

Such a gradual advance toward general recognition is well illustrated by the history of multiple neuritis, which is to engage our attention at the present time.

I think we may claim that one of the first cases presented was by an American physician, Dr. James Jackson, of Boston, in 1822.[1] In a paper "On a Peculiar Disease Resulting from the use of Ardent Spirits," which he named arthrodynia, he gives a most graphic picture of what we now know to be one form of multiple neuritis. He says, "This disease comes on gradually. It commences with pain in the lower limbs, but especially in the feet, and afterward extends to the hands and arms. The hands may be affected first in some instances, and in all cases in an advanced state the pain is more severe in the feet and hands than in the upper part of the limbs. The pain is excruciating, but varies in degree at different times. It is accompanied by a distressing feeling of numbness. After the disease has continued a short time, there take place some contractions of the fingers, and toes, and inability to use these parts freely. At length the hands and feet become nearly useless, the flexor muscles manifesting, as in other diseases, greater power than the extensors. The whole body diminishes in size, unless it be the abdomen, but the face does not exhibit the appearance of emaciation common to many visceral diseases. The diminution is especially observable in the feet and hands; and at some time the skin of these parts acquires a peculiar appearance. The same appearance is noticed in a slighter degree in the skin of other parts. This appearance consists in a great smoothness and shining with a sort of fineness of the skin. The integuments look as if tight and stretched, without rugæ or wrinkles, somewhat as when the subjacent parts are swollen; but the skin is not discolored. Yet in this disease there is not any effusion under the skin, and the character which this assumes

[1] The Middleton Goldsmith Lectures, delivered under the direction of the New York Pathological Society, January 25, 1887.

[1] New England Journal of Medicine and Surgery, vol. xi., p. 351.

arises from some change in the organ itself. The most characteristic symptoms are manifested in the limbs, but the pain is not limited to these—and other symptoms are exhibited in other parts. The pain sometimes shoots suddenly up one or both legs, and in one case it frequently passed up the back and then forward to the pit of the stomach. The functions of the stomach are always impaired. The mind is weakened. Sleep is prevented by pain. I believe that this disease is always fatal when the use of spirituous liquors is not abandoned before the powers of the digestive organs are greatly impaired."

It is hardly possible, even at the present day, to add to this description, which portrays in strikingly vivid language the main features of one form of multiple neuritis.

The next observations of importance in establishing a clinical picture were made by Magnus Huss, who, in his work upon chronic alcoholism, in 1852, gave a very complete description of alcoholic nervous symptoms, dividing the cases into paralytic, anæsthetic, convulsive, epileptic, and hyperæsthetic forms. But not content with the clinical side, he advanced to pathological hypothesis, and ascribed all the various symptoms to lesions in the central nervous system. His description was amplified and completed by Lancereaux, in 1864, in an article upon alcoholism in the "Dictionnaire Encyclopédique des Sciences Médicales." But the pathology of the disease was still a matter of speculation.

In 1855 the great work of Duchenne was published,[1] and in it a number of cases are recorded which we now recognize as multiple neuritis. In these cases there were sensory disturbances, consisting of pain, numbness, and loss of sensation; motor disturbances, consisting of paralysis, with atrophy, especially marked in the distal parts of the extremities, and attended by a loss of faradic contractility in the paralyzed muscles; and cyanosis, coolness, and increased sweating in the affected limbs. Duchenne grouped these cases together under the title "Paralysie Générale Spinale Subaigue Ascendante," because he thought a gradually advancing lesion in the spinal cord, from below upward, would explain the symptoms. It is true that he found no macroscopic change in the cord in the only case in which he made an autopsy. But when, under the leadership of the French school, from 1860 to 1865, the microscopic appearances in nervous lesions began to be studied, the hypothesis of Duchenne at once appeared to be verified, for it was found that such symptoms as numbness, pain, and anæsthesia were associated with lesions of the posterior columns of the spinal cord. And it was also proven that atrophic paralysis was caused by a degeneration of the ganglion-cells of the anterior gray horns of the cord, not necessarily visible to the naked eye. It seemed an easy step to the conclusion that when these symptoms occurred together the entire spinal cord was the seat of disease, and that wherever they occurred a spinal lesion was progressing. The pathology of this form of paralysis appeared to be definitely ascertained, and for many years the fallacy of such a conclusion was not detected. All atrophic paralysis was invariably referred to spinal lesions, because spinal lesions may cause atrophic paralysis.

But facts rarely accommodate themselves permanently to theories, and after a time a mass of very unwieldy facts began to accumulate. Cases of atrophic paralysis without spinal lesion were observed, and these threw doubt upon the theoretical pathology. The period of true pathological observation had begun, and gradually went on to completion. In 1864 Dumenil reported the following case, which deserves to be cited, as it is the first in which an autopsy established the existence of a wide-spread disease in the peripheral nerves as a cause of sensory, motor, and trophic symptoms.

Observation I.—A tailor, aged sixty-one, after suffering from prickling in the toes for two weeks, was suddenly taken with weakness in the left arm and right leg, and, a few days later, by the same paresis in the left leg. Within five days he could not stand or walk. The paralyzed feet hung flaccid, and were totally paralyzed; the thighs could be moved freely. Anæsthesia was found on the right sole and calf, and on the left foot and outer side of the leg. In the muscles of the hands and forearms a considerable atrophy, with paralysis, developed. The faradic contractility was abolished in the paralyzed muscles. He complained of a painful numbness in the paralyzed limbs up to the knees, and involving the hands. No improvement; death in four and a half months.

Autopsy: Spinal cord and nerve-roots were normal. The finer nerve branches in the legs and hands were degenerated, only a small number of nerve-fibres being found. Single fibres showed no continuous myelin sheath; but this was segmented and granular. There was an increase of connective tissue, and many fat-cells in the nerves.[1]

This case being of an anomalous character excited very little attention. Two years later, however, Dumenil reported another, and published an elaborate article on peripheral paralysis, in which he said: "My own observations have convinced me firmly that many paralyses of obscure origin are caused by true spontaneous neuritis."[2] The second case, which with the first led to this conclusion, has been cited by Leyden as a case of neuritis, but it does not conform to any of the types of multiple neuritis, and is open to some doubt from the results of the autopsy, since numerous foci of disease were found in the spinal cord. We therefore pass it by.

Singular as it may seem, an interval of ten years elapsed before another case of similar nature, accompanied by a record of *post-mortem* examination, appeared. Then Eichhorst, of Berlin, reported the following interesting history:

Observation II.—A female, aged sixty-six, after suffering daily for two weeks from a chill, fever, and sweat, attended by malaise, anorexia, and constipation, noticed an œdematous swelling of both feet and legs, and complained of pain in the abdomen. A week later, on admission to the hospital, these symptoms continued. The urinary examination was negative. Three days after admission she suddenly felt a severe boring pain in the left leg, shooting into the toes, and at the same time a profuse sweat broke out over the calf and back of the foot. A few hours later a total paralysis was found in the muscles supplied by the peroneal nerve, with a marked anæsthesia. The electric reaction, at first preserved, was found two days later to be gone. After six days, during which she had no further chills, a paralysis of the anterior tibial nerve developed, and soon after of the posterior tibial nerve also. One week later entire paraplegia of the legs, with anæsthesia, severe pains, continual sweating, increasing œdema, and loss of the tendon reflexes had ensued. There followed a paralysis of the left, and soon after of the right, radial nerve. Moderate fever continued, and albuminuria appeared. Three weeks after her admission sudden blindness developed, the ophthalmoscopic appearances being at the time normal; the patient then lay in bed with eyes closed, unable to move a limb. The extremities perspired constantly, and were tender, any pressure on nerve-trunks being very painful. In the face there was no trouble, and the senses were normal except that of sight. No trouble in swallowing. Nothing abnormal about the viscera during the entire disease. No irregularity of pulse or respiration. Death occurred on the forty-fourth day of the disease.

Autopsy: Spinal cord absolutely normal. The nerve-trunks in the bicipital grooves appeared intensely red to

[2] Ceque j'ai observé me donne la conviction intime que bien des paralysies de cause obscure ont leur point de départ dans les véritables névrites spontanées, Gaz. Heb., 1866, No. 4.

the eye, the perineurium being discolored and the endoneurium blood-red. The same appearance was noticed in the large nerve-trunks of the arm in their course, as well as in the left tibial nerve. The microscopic examination showed a remarkable distention and tortuosity of the blood-vessels of the perineurium; the vessel-walls were thickened, their nuclei increased. In the vicinity of the vessels a large number of lymphoid cells were found, which everywhere followed the vessels and infiltrated the connective tissue. There were also numerous fatty cells. The connective-tissue fibrillæ of the perineurium were thickened, shining, and swollen; their nuclei were increased and partly infiltrated with fat granules. Similar changes were seen in the endoneurium, viz., numerous extravasations of blood, which separated the nerve-fibres and compressed them. The nerve-fibres showed marked degeneration, especially those lying next the endoneurium, consisting of disintegration of the myelin sheath, and a distention and spindle-shaped swelling of the individual nerve-fibres. The nuclei of the sheath of Schwann were not increased in number, but the protoplasm about them was coarsely granular and opaque. The cells of the endoneurium were everywhere wanting, being replaced by fatty granular cells, even between the uninjured fibres.[1]

This is the first case to be found in which the microscopic appearances are described with sufficient detail to be satisfactory. It is to be noticed that here the lesion was an acute inflammation, and was, apparently, a diffuse one, both interstitial tissue and nerve-fibrils being involved in the process. That it was primarily an interstitial inflammation, and that the affection of the nerve-fibrils was secondary, due to pressure of the products of exudation, is clearly seen in the fact that those fibres were more seriously affected which lay near vessels, while the deeper fibres in large bundles were not at all degenerated. The appearance of the fibres was such as occurs in any degeneration from pressure. There is no reason, therefore, to believe that the process began diffusely.

As to the symptoms in this case, it is to be remarked that they were ushered in by an acute febrile movement with chills, and that severe pain was an early and prominent symptom; also that œdema and sweating were present; and that the optic nerves were involved.

The clinical picture in the following case of Joffroy, published three years later, was somewhat different, as was also the pathological condition.

Observation III.—A washerwoman, aged thirty-three, in the last stage of phthisis, was admitted to the hospital on March 5th. In February she had noticed a rapidly increasing weakness of her legs, and at the time of admission she could not walk or raise her feet from the bed. She could flex the knees but not extend them. There was no contracture, and the muscles were relaxed and flabby. Sensations to pain, temperature, and pressure impressions were normal, but the muscular sense was lost, and reflexes were diminished. She showed such a degree of mental weakness that tactile sense could not be tested. She had no shooting pains, no loss of control over bladder and rectum, no bedsores. Two weeks later the arms became involved in the paralysis, and atrophy, inco-ordination, and loss of muscular sense, with fibrillary motions, developed within a few days. There was great diminution of faradic excitability in all the paralyzed muscles. At the end of ten days the arms were entirely powerless, but retained their sensibility. On April 7th she died.

Autopsy: A chronic meningitis of the brain explained the mental symptoms. The spinal cord was normal. The nerves appeared normal; but microscopic examination showed very marked degeneration in all the nerve-trunks, but especially in the sciatic, radial, and ulnar nerves. There was a segmentation of the myelin sheath, which at places was reduced to a finely granular mass. Many sheaths of Schwann were filled with this mass, others were empty, The nuclei of the sheaths of Schwann were increased in number. All the spinal nerve-roots were normal. The changes in the nerves were followed down into the fine terminal branches in the thenar muscles. The muscles were atrophied and showed fatty degeneration.'

Here, in contrast with the preceding case, it is to be noted that the lesion was not attended by congestion of the nerves, or by any exudation of lymphoid cells, or by marked interstitial changes. The affection was a true parenchymatous inflammation, with degeneration of the myelin sheath and axis cylinder. As a result, the macroscopic appearance of the nerves was not such as to attract attention, and it required a microscopic examination to demonstrate the changes present. Joffroy, who reports this case as one of general spontaneous neuritis, finds the lesion identical with that observed in cases of localized neuritis occurring from cold, from lead palsy, or as a sequel of the infectious diseases. In regard to the symptoms, also, the case contrasts strongly with the preceding one. The patient had phthisis. The disease advanced more slowly. Pain was absent, and the sensory symptoms were by no means prominent, the muscular sense being the only one affected.

In 1880, the following cases were observed by Leyden, in the Charité Hospital of Berlin, in both of which changes were found in the peripheral nerves. They are cited because they not only enlarge our clinical picture, but confirm the pathological conditions already described.

Observation IV.—A sailor, aged twenty-five, was suddenly seized with severe tearing pains in all four extremities, especially near elbows and knees, which were swollen, white, indurated, and very tender. The pains shot down the limbs, and were attended by formication and by diminished sensation in fingers and toes. High fever accompanied the onset. In a few days, as the fever subsided, a paretic condition with muscular atrophy was noticed in the forearms, and to a less extent in legs and feet. A gradual improvement took place in the course of a few months in the lower extremities, but the paralysis and atrophy in the arms increased in degree, and the appearance of the hands resembled that seen in lead palsy. There was a reaction of degeneration in the muscles paralyzed. A year after the onset he died of chronic nephritis.

Autopsy: A sclerotic atrophy of both radial nerves was found. The nerve-sheath was thickened. The muscles were considerably atrophied. The anterior spinal nerve-roots, as well as the cells in the anterior horns, and the entire spinal cord, were normal. In the nerves of the lower extremities no changes were visible.[2]

Observation V.—The second case was that of a merchant, aged thirty-one, who noticed about Christmas, 1878, a feeling of formication in the toes and sole, of first the left, and then the right foot. This continued more or less severe, without any motor disturbance, until July 10th, when he found his legs heavy, and in two days this had so increased that he could not walk. At the same time a constant formication in the soles of the feet was felt. Within a few days similar symptoms appeared in the arms and hands. On admission to the hospital on July 17th, he complained of weakness of the legs and loss of sensation in the hands, also burning pain in the left hand and inner side of the left knee. The motion of the legs was powerless and uncertain, and there was paresis of the extensors of the hands and fingers. Sensation was much impaired in the periphery of the extremities; the tendon reflexes were abolished, the muscles flabby. The electrical examination showed a loss of faradic contractility, and a great diminution of galvanic contractility in the affected muscles. The liver was tender, and there was a slight jaundice; pulse 70; no fever. The paralysis

[1] Eichhorst: Virchow's Archiv, Bd. 69, p. 265. 1876.

[1] A. Joffroy: Arch. de Phys. norm. et path., 1879, pp. 172–198.

[2] Leyden: Charité Annalen, 1880.

increased slowly in extent and severity, and was accompanied by paræsthesia, pains, and diminished sensibility. The muscles atrophied, and showed the reaction of degeneration. After six weeks slight fever began, with rapid pulse aud dyspnœa. The pains affected the upper part of the thorax, and the spinal column became sensitive as low as the eighth dorsal vertebræ. During the last days small rapid pulse, severe dyspnœa, purely costal respiration, delirium, somnolence, and exhaustion were noticed, and on September 3d he died.

Autopsy: The spinal cord was normal, the gray and white substance intact, the large ganglion-cells in normal form and number, though a few seemed to present a slightly swollen, glassy appearance which Leyden considered the first indications of trophic disturbance. The nerve-trunks, especially the radials and peronei, presented the appearance of a high degree of fatty degeneration and atrophy. The myelin sheath was either wholly wanting or greatly divided and split up, and in a state of fatty degeneration; the axis cylinder seemed varicose from deposits of fat in it. A marked infiltration of lymphoid cells, especially between the endoneurium and nerve-fibres, was noticed, more marked along the course of the small arterioles. These changes were present in a greater degree in the peripheral branches of the nerves, and seemed less in the nerves near the cord.[1]

It will be noticed that here the lesion corresponded quite closely to that in the case of Eichhorst.

Impressed by the striking features of these two cases, and by their similarity, both in clinical symptoms and pathological changes, to the cases of Dumenil, Joffroy, and Eichhorst already cited, Leyden undertook a review of atrophic paralysis.[2] He showed the confusion which had come from blindly referring all such cases to a single lesion in the spinal cord. He proved that previous authors had erroneously grouped together several diseases distinct from one another, both in their course and in their pathology. One of these is poliomyelitis anterior, acute and chronic, occurring in children and adults; a disease of the anterior gray horns, with local foci of inflammatory degeneration; a disease characterized by motor and trophic symptoms of peculiar distribution and typical course. A second of these is progressive muscular atrophy, with its corresponding bulbar affection, glosso-labio-laryngeal paralysis; a disease of the anterior gray horns and of the motor cranial nerve-nuclei, of a chronic degenerative, non-inflammatory kind; a disease characterized by trophic and motor symptoms of different distribution, nature, and progress from the first disease considered. A third disease is pseudo-hypertrophic paralysis, in which a fatty deposit in the muscle conceals the real atrophy in progress; a disease of childhood, but not due to any spinal affection; a disease of the muscular tissue itself. And lastly, he drew the picture of multiple neuritis, a disease due to degenerative processes in the nerves, independent of spinal lesion; a disease characterized by atrophic paralysis, associated with marked sensory symptoms, and with tenderness of the nerve, by a typical course, and, usually, by a favorable termination. By this article Leyden established the status of multiple neuritis as a distinct disease. Its symptoms were analyzed. Its lesion was described. The pathological stage in the progress of its discovery was complete.

When the characteristic features of a new disease have once been clearly pointed out, it is remarkable to observe how rapidly cases of it begin to be recognized. In the two or three years which followed the appearance of Leyden's article, numerous cases of multiple neuritis were reported in the journals. And many physicians, reviewing their records, recognized, in cases previously obscure or imperfectly diagnosticated, typical pictures of the new disease. It may be well to consider a few of these cases in order to complete our clinical knowledge of the affection.

Observation VI.—A female, aged thirty, of intemperate habits, but otherwise in good health, after suffering from formication, coldness, and pains in her feet and legs for some months, noticed an œdema of both legs. This increased rapidly after a few days, and the swollen limbs became painful to touch or pressure, and were the seat of severe lancinating pains, which were worse at night. Within a month the same symptoms appeared in the arms and hands, and a marked hyperæsthesia developed in all the extremities, as well as a rapidly progressing paralysis; so that, on admission to the hospital, six weeks after the appearance of the œdema, it was impossible for her to lift her limbs from the bed, or to extend her hands and fingers. The movements in the distal portions of all the extremities were much more impaired than those near the trunk, and in the paralyzed extensor muscles the faradic excitability was almost abolished. Heart and kidneys normal. She had some fever, and was delirious at night. The symptoms increased rapidly; the paralysis became total; respiration became difficult; the heart rapid, and a week after admission to the hospital she died.

Autopsy: Tubercles in the lungs. Brain and cord were normal. Nerve-roots were normal. In the nerves of the extremities marked degeneration was found, especially in the radial and tibial nerves. By the side of a small number of empty sheaths were found fibres, whose myelin was segmented and in drops, separated by empty spaces. The axis cylinders were indistinct. There was no increase in the nuclei of the sheath of Schwann.

In discussing the case Dr. Lancereaux made the diagnosis of alcoholic paralysis, assigning the lesion to the nerves, and differentiating it from a myelitis or a meningitis. In so doing he criticised the view of Wilks and Lockhardt Clarke, who still considered alcoholic paralysis as a central disease. He cited another case, very similar, of a female aged thirty-three, in which the symptoms were pains, hyperæsthesia, tenderness, paralysis, with atrophy in the extremities, but in which œdema was not so marked and came on quite late in the course of the case. The same lesions were found. To these he added two cases in which the patients manifested the same symptoms, but had never drank. They were both, however, sellers of varnish, and lived day and night in an atmosphere permeated by alcoholic vapor, from which he concludes that chronic alcoholic poisoning can occur by absorption through the lungs—a valuable observation, but hitherto not confirmed.[1]

The following case was reported by Grainger Stewart, together with two other cases which resulted in recovery.

Observation VII.—A male, aged thirty-one, noticed during August, 1880, a weakness of the legs, and during the following month a pain of a prickling character in the legs and feet. These increased in intensity, and in October a similar feeling came on in the fingers and hands, accompanied by loss of power and stiffness. When seen, in November, he had tingling pain in both legs from the knee to the back of the foot, with numbness and feeling of cold in the toes and plantar surfaces, so also in the hands, to a less extent. No girdle pain or formication. Sensibility to touch was diminished in the legs and hands. Transmission of impressions was delayed. Sensibility to heat, tickling, and pain were all diminished, as was also the muscular sense in the feet. There was no nystagmus, although he complained of things dancing before his eyes. Sight was normal. There was no incontinence of urine or fæces. The skin reflexes were absent in the soles, but normal in the abdomen and groins. The knee-jerk was absent. Voluntary motion was greatly impaired in legs and arms, and attempts to use the muscles caused pain. Electric irritability of the

muscles and sensibility of the skin was much diminished. There were no vaso-motor or trophic changes. His mental condition became changed during his stay, his memory was impaired, and he seemed drowsy. A month after his first examination he died of pneumonia.

Autopsy by Dr. D. J. Hamilton: The median, ulnar, and tibial nerves showed great changes. With a low power of the microscope the bundles of fibres appeared to be affected by fatty degeneration. With a high power it was found that the axis cylinders were swollen so as to form a number of fusiform bodies in the course of the nerve-tubes. These at parts were divided into a number of round homogeneous colloid bodies. When set free these bodies underwent a fatty degeneration, forming compound granular corpuscles. In some fibres the axis cylinder was totally destroyed, nothing but a quantity of fibrous tissue remaining. The cords of the brachial plexus and the sciatic nerves were normal. Slight evidence of secondary sclerosis in the spinal cord was found in the columns of Goll and in the direct cerebellar columns. Its origin could not be explained.[1]

It must not be supposed, from the fact that all the cases so far cited were fatal, that death is always the result in multiple neuritis. This is very far from the truth, and probably, if the mortality had been greater, the pathology of the disease would not so long have eluded search. The fatal cases have been brought together in order that the pathological appearances observed might be noted and compared, and might become somewhat familiar by repetition. It is time to enter upon the more careful study of their pathology, and so, for a time, let us leave the clinical features of the disease.

It may not be out of place, before proceeding to discuss the changes occurring in inflammations of the nerves, to review the normal anatomy of a nerve.

THE HISTOLOGY OF A NERVE-FIBRE.—When a nerve-trunk is dissected, the connective-tissue sheath or perineurium enclosing its fibres torn away, and the individual fibres set free by teasing from the finer connective-tissue strands or endoneurium which bind them together, it is possible to distinguish certain parts, by means of appropriate methods of staining.

There is *first* the axis cylinder, Fig. 1 (*a*). This is made up of a number of primitive fibrils arranged longitudinally and continuous throughout the length of the nerve. The fibrils are cemented together by a substance which appears finely granular. Each cylinder is supposed to represent a prolongation of a single nerve-cell; but whether the individual fibrils of which it is made up come from the same cell or from different cells, or from the fibrillary network in the central organ surrounding the cell, is a matter of hypothesis.[2]

FIG. 1.—A Normal Nerve-fibre. *a*, Axis-cylinder; *b*, medullary sheath: *c*, sheath of Schwann; *d*, node of Ranvier; *e*, incisure of Schmitt: *f*, nucleus of the sheath of Schwann.

There is, *secondly*, the myelin sheath surrounding the axis cylinder, Fig. 1 (*b*). This is not a continuous tube, but consists of a series of little tubes, or interannular segments, placed end to end. The point of junction of two adjacent segments is indicated by a constriction in the contour of the nerve-fibre, and if the myelin be stained with osmic acid it is seen to be deficient at these constrictions. If, by any means, the nerve-fibre be broken, the myelin in any segment will run out and collect in drops, showing that it is a semi-fluid substance, of fatty nature.[1]

There is, *thirdly*, a connective-tissue membrane surrounding the myelin sheath, the sheath of Schwann, Fig. 1 (*c*). This, like the last, is made up of segments cemented to one another at the point of constriction of the fibre. This constriction is known as the ring or node of Ranvier, Fig. 1 (*d*), and at its situation the sheath of Schwann is the only covering of the axis cylinder. On the inner side of this sheath, and half-way between two nodes, is found a nucleus, Fig. 1 (*f*). The sheath and node are made evident by staining with nitrate of silver, while the nucleus is seen best by staining with carmine or acid fuchsin. The mutual relation of the sheath of Schwann and the myelin sheath, are best understood by the study of their development, segment by segment. Ranvier[2] likens the production of any one segment of these sheaths to the production of a fat cell from a nucleated cell. Every nucleated cell is surrounded by a layer of protoplasm. As the fat forms it collects within the layer of protoplasm in the vicinity of the nucleus, in the form of drops which finally unite into a mass. This mass is surrounded by a very thin layer of protoplasm and by the cell-membrane. On one side of it is seen the nucleus flattened out against the inner side of the membrane in the layer of protoplasm. Now, if each segment of the sheaths corresponds to the fat cell, and the myelin to the fat, the structure of the segment is clear. The membrane of the fat cell is represented by the sheath of Schwann. At the point of constriction of the nerve-fibre this membrane is cemented to that of the adjoining segment. Beneath the membrane, and flattened against its side, is the nucleus of the segment, lying in a layer of protoplasm in the middle of the segment. This layer of protoplasm forms a lining everywhere to the sheath of Schwann. With that sheath it is reflected around the axis cylinder. Within the lining, in a state of semi-fluidity, is contained the myelin, which will run out if the limiting membrane is broken. By appropriate staining fine lines can be seen passing between the outer and inner layers of protoplasm, through the myelin sheath, the so-called incisions of Schmidt, Fig. 1 (*e*). These have been considered little trabeculæ of protoplasm within the segment in the midst of which the myelin lies. Recent staining methods seem to indicate that they belong to the sheath of Schwann and are connective tissue. The layer of protoplasm lying against the axis cylinder is the layer which was formerly described as the sheath of Mauthner. Some authorities consider that a layer of connective tissue similar to the sheath of Schwann surrounds the axis cylinder, but this is still uncertain. Thus the nerve-fibre consists of a central conducting strand, surrounded and insulated by a series of tube-like segments of fluid contained within a membrane, which are joined to one another, forming a double protecting sheath.

Individual fibres are associated in bundles held together by fine connective-tissue cells whose nuclei can be seen in a carmine or fuchsin stained preparation, lying always adjacent to, but outside of, the sheath of Schwann.[3] This has been called the endoneurium, while the connective-tissue sheath surrounding the entire bundle is named the perineurium. Capillary vessels with free anastomoses run within the nerve, their walls lying adjacent to the in-

[1] Grainger Stewart: Edinburgh Medical Journal, April, 1881.

[2] Whatever their origin, it is certain that they pass together in the axis cylinder to the periphery, and that there the axis cylinder as such terminates, while the individual fibrils branch out in various directions, and, joining with other fibrils from other cylinders, form a fine plexus within the organ to which the nerve as a whole has gone. It has been thought possible to trace individual fibrils of the plexus into individual epithelial cells. Such is their termination in various internal organs and in the skin. This is not, however, the only manner of termination of the axis cylinder, for individual nerves can be traced directly to terminal organs, such as the terminal plates upon the muscle, and the terminal bulbs and corpuscles in the skin; in which cases no division or branching of the fibrillary constituents of the axis cylinder has been discovered. The termination in each of the organs of special sense is still different. The axis cylinder can best be seen by the acid fuchsin stain.

[1] The myelin sheath is not a necessary constituent of all nerve-fibres, for the majority of the nerves of the sympathetic system are devoid of such sheaths. Nor does the myelin sheath of the nerves of the cerebro-spinal system extend from end to end of the axis cylinder. For the axis cylinder first receives its sheath at some little distance from the cell from which it issues, and at its termination, where it breaks up into branching fibrils, the myelin envelope ceases. Throughout the course of the nerve, however, the myelin sheath is present in the cerebro-spinal nerves, forming a protecting envelope, and probably acting as an insulating substance as well.

[2] Ranvier: Leçons sur l'Histologie du Système Nerveux. tome i., p. 115.

[3] These connective-tissue cells which lie between individual fibres have been recently the subject of study by Adamkiewicz (Adamkiewicz, Ueber Ruckenmarkschwindsucht, Sitzungsbericht der Wiener Acad., Bd. 91, Abth. II.), and Rosenheim (Rosenheim, Arch. für Psych., xvii., p. 830). The former regarded them as nerve-corpuscles, but the latter has proven that they are true connective-tissue cells. They are best seen in specimens stained with a double staining of

dividual fibres, and thus affording a perfect nutrition.[1] Lymph-spaces also have been demonstrated within the nerve-sheath, but not among the fibres.[2] That the interfibrillary spaces of the endoneurium, however, open into these peri-fascicular lymph-spaces is probable, from the fact that they do so in other organs. While it is evident that the nutrition of the axis cylinder is derived from the circulatory fluids, it is probable that it is only at the nodes of Ranvier that the absorption takes place, since elsewhere the myelin sheath interferes with osmosis. Thus, if the nerve be put in nitrate of silver, it is only opposite the nodes that the axis cylinder becomes stained.

The Pathology of Multiple Neuritis.—In studying the pathological processes which occur in multiple neuritis, it is necessary to keep these various elements of the normal nerve in mind, since each element is subject to changes. The exact character of these changes is best understood by observing the results of nerve-degeneration artificially produced in animals. And a study of this will not be out of place here, for, as we shall see, the changes occurring in multiple neuritis correspond quite exactly to those produced by experimental degeneration.

In considering the pathology of degenerative neuritis we enter at once upon a mass of controversial statements. It would seem to be a simple matter to establish, by observations upon nerves which had been experimentally compressed or severed, the changes which ensue in nerve-injuries. But, as a matter of fact, there is, perhaps, no field of experimental pathological inquiry in which the results have differed more widely. In the first place, it is probable that the rapidity and even the character of the changes differ in different animals. Secondly, various methods of investigation, of hardening, dissecting, and staining the nerves, seem to have resulted in the production of different appearances. And, lastly, it is by no means certain that a uniform pathological process goes on after experimental lesions.

After a lesion of a nerve-trunk, a process of degeneration sets in at the point of injury, and involves a small portion of the central end and the entire peripheral part of the nerve, from the seat of injury onward. This process may be more or less complete, and may, or may not, be followed by a second process of regeneration in the diseased nerve. It is necessary to distinguish between the degenerative and regenerative processes; and, inasmuch as it is affirmed that they may proceed simultaneously in various parts of the same fibre,[3] it is not strange that the confounding of the two should have increased the confusion in the statements.

In early times it seems to have been a question whether the destruction of a nerve was ever recovered from, and while the majority of authorities rightly contended that this was possible, there were those who denied it vehemently. Steinneck,[4] in 1838, seems to have determined this finally in the affirmative, using both the physiological and anatomical data at his disposal to good advantage. The exact processes of degeneration were first carefully studied by Nasse[5] and Waller,[6] and their results having attracted attention to the phenomena in question, a host of investigators have followed their lead. The most careful examinations of the entire series of changes which go on in degeneration and regeneration have been made by Ranvier,[7] Philipeau and Vulpian,[1] and Dejerine,[2] in France; by E. Neumann,[3] S. Mayer,[4] and Wolberg,[5] in Germany; by Hanken,[6] in Holland; by Schiff[7] and Tizzoni,[8] in Italy, and by Weir Mitchell,[9] in America.

The majority of writers upon nervous diseases and upon general pathology seem to have followed Ranvier closely, without any mention of the fact that other authorities differ from his conclusions. It will be necessary here to present the various views which are held.

The Process of Degeneration.—When a nerve is compressed by a ligature or forceps without sufficient force to rupture the sheath of Schwann, the myelin is driven away from the point of pressure in both directions, and the axis cylinder is disintegrated and mingled with it. It might be supposed that the nodes of Ranvier would prevent such a driving back of the myelin, but they seem to offer but feeble resistance, so that the entire fibre on either side of the compressed spot is bulged out for some little distance, the sheath of Schwann between the distended portions being left empty or containing only a little granular débris. In a short time changes of a degenerative character are observed on both sides of the point of compression. Those on the central side are limited to the immediate neighborhood of the injured spot, and, according to Ranvier, do not affect the nerve for a distance greater than a centimetre from the point of compression.[10]

On the peripheral side of the point of pressure the degeneration is extensive, involving the entire nerve down to its finest terminations. The process is held by some to be a gradually advancing one along the fibre from the point of pressure outward, while others believe that it begins at once in the entire length of the nerve. The first change noticed is a breaking up of the myelin sheath into segments, and then into smaller masses and drops (Fig. 2, *a*, *b*), which finally undergo further disintegration, either by a fatty or albuminoid degeneration, or by a process of saponification, until a finely granular mass alone remains. Tizzoni states that this process is partly due to the activity of migratory white blood-globules, a view which Ranvier supports, and which Neumann and Mayer deny. If, as seems probable, the connective-tissue cells of Rosenheim take an active part in all processes of nerve inflammation, it is possible that these are the bodies which Tizzoni mistook for leucocytes. Ranvier holds that the segmentation of the myelin is due to the increase of the protoplasm about the nucleus of the segment, and that it is this protoplasm which replaces the myelin. Neumann holds that the granular mass resulting from the disintegration is not protoplasmic, but is a débris capable of acting as the basis for processes of regeneration after undergoing a chemical change. All authorities admit that the granular mass may be gradually absorbed, leaving the sheath of Schwann collapsed and empty, or containing only granules of débris or nuclei (Fig. 2, *c*, *d*).

As the myelin undergoes these changes the axis cylinder

---

anilin, gentian violet and methyl blue, though they can be seen distinctly in fuchsin stained preparations, as has recently been demonstrated by Dr. Van Giesen, of the Laboratory of the College of Physicians and Surgeons. They appear on nerves after the age of five, and increase in number as the individual grows older, so that in elderly persons they are very numerous. They are round or spindle-shaped, and frequently appear to have little thorn-like processes. In addition to these connective tissue cells there are fine fibrils of connective tissue, and bands of tissue lying between the bundles of nerve fibres.

[9] Injuries of Nerves, 1872.
[10] Some recent investigations of Friedlander and Krause throw doubt upon this statement. (Fortschritte der Medicin, December 1, 1886). They have discovered a considerable degree of atrophy in the nerve-trunks in the stumps of amputated extremities, and they traced this atrophy upward through the nerves, and into the posterior nerve-roots exclusively. They conclude, therefore, that the fibres affected are entirely sensory fibres. The axis cylinder is only slightly affected by the atrophy, but the myelin sheath is wholly destroyed. Inasmuch as the degree of atrophy in a nerve-trunk was about the same whether the amputation had been made near the body or near the end of the limb, they conclude that only certain of the sensory fibres degenerate upward. And as the tactile corpuscles and terminal bulbs are only found in the most distal parts of the extremities, it is suggested that only those sensory fibres degenerate which arise from these so-called tactile bodies. If this is proven to be true by further observation, the tactile bodies will assume the role of trophic centres for the sensory nerves. And in this case anything which interrupts the connection between the tactile bodies and the posterior spinal ganglion will produce a centripetal degeneration in the nerve. Hence in neuritis from section or pressure, as well as in multiple neuritis, such secondary degeneration is to be expected and should be looked for.

usually becomes involved. Some authors, it is true, believe that it remains intact, and that, although deprived

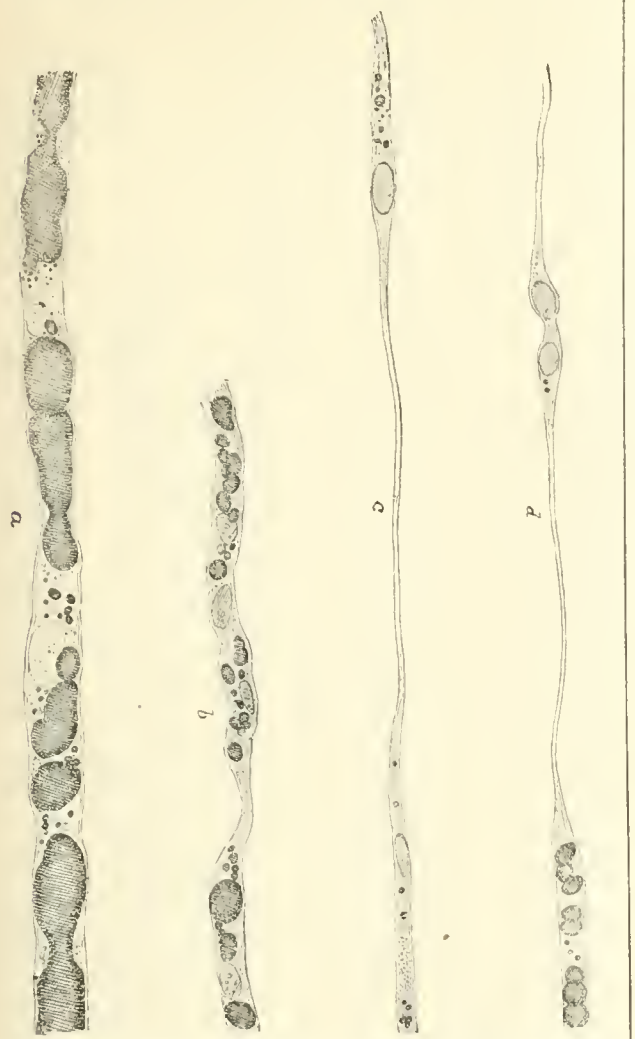

FIG. 2.—The Process of Degeneration. (After Ranvier.) *a*, Segmentation of myelin an daxis-cylinder, with increase of protoplasm; *b*, disintegration of myelin into drops, increase of nuclei, partial absorption of débris; *c*, complete absorption of the disintegrated mass, leaving the Schwann sheath empty, or containing only débris and nuclei; *d*, the same, nuclei alone remaining.

of its function, it is capable of resuming that function at any time when regeneration of the myelin sheath has taken place. Such authorities as Erb, Charcot, Weir Mitchell, and Wolberg have given their approval of this view. Ranvier believes that the protoplasm of the nucleus attacks and destroys the axis cylinder as well as the myelin. Neumann holds that it is split up into segments like the myelin, becomes mingled with it, and undergoes the same process of chemical change, or absorption; and Mayer agrees with this view. (Fig. 3, *a*, *b*, *c*.)

The sheath of Schwann also takes part in the process of degeneration. When that process has fairly begun numerous nuclei are observed lining this sheath in each interannular segment. They may have come by a process of segmentation of the original nucleus of the segment, as Ranvier holds. But Neumann and Mayer have shown that they appear as early at the extremities of the segment as they do in the vicinity of the nucleus, and they therefore conclude that they are a free formation originating in the granular or protoplasmic mass. Tizzoni thinks them emigrated corpuscles. The most recent view of all is that of Rosenheim, that they come from the connective-tissue cells along the sheath which divide and multiply, and show powers of emigration as soon as the process of degeneration begins. When the granular mass is absorbed these nuclei remain scattered along the sheath of Schwann, and it has been suggested that, when in an empty sheath a new axis cylinder appears, it owes its existence to these nuclei, which arrange themselves in a line and develop into the new fibre (Wolberg). If no regeneration occurs they disappear gradually, and then the only relic of the former nerve-fibre is the empty, collapsed sheath of Schwann, which remains as a connective-tissue strand.

The increase of nuclei and connective-tissue fibrils in the endoneurium and perineurium which accompanies the process of degeneration, aids in the transformation of the nerve into a band of connective tissue.

The degeneration which affects the nerve is continued to the terminal plates upon the muscle, and these are changed into a mass of granules and finally absorbed, a connective-tissue plate being left.[1] Whether any changes occur in the sensory terminal organs, such as the tactile corpuscles or terminal bulbs, has never been ascertained. Those who believe that the individual axis cylinder fibrils terminate in the epithelium of the skin may cite the trophic changes which often occur on the surface as evidence that this covering of the body shares in the nerve changes.

Authorities seem to agree that the same results follow a division of a nerve that are observed after its compression, with the difference that at the point of section the myelin runs out of the sheath of Schwann. The cut central end of the nerve becomes swollen into a bulbous extremity by a growth of connective tissue.

Whether a true union of the divided ends ever occurs is still a matter of uncertainty. The majority of authori-

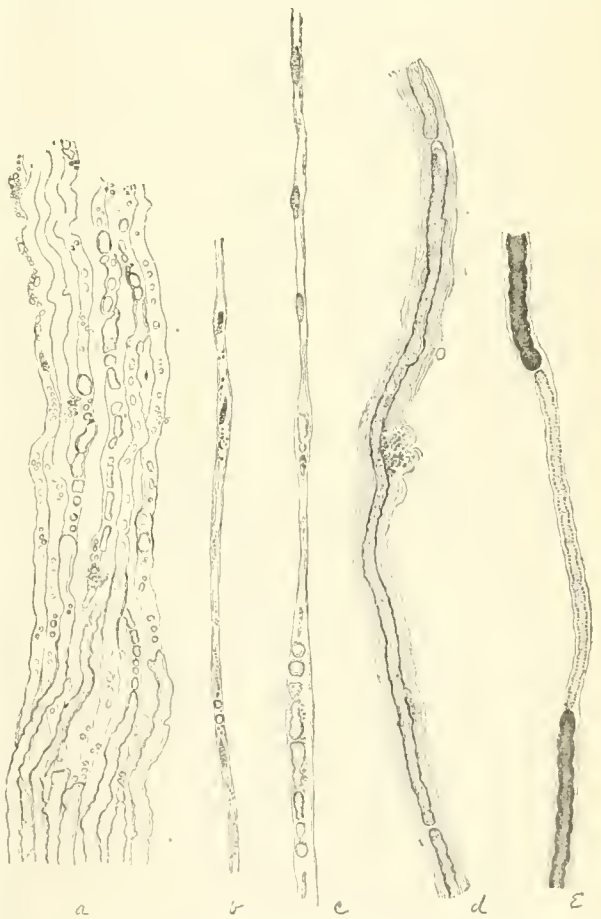

FIG. 3.—The Process of Degeneration and Regeneration going on in Normal Nerves. ties, following Ranvier, affirm that while a primary coaptation of the ends by an exudate which is secondarily transformed into connective tissue may occur and hold the ends in position, no true primary union of nerve-

[1] Gessler: Die Motorishe Endplatte und ihre Bedeutung fur die Periphere-Lähmung. Leipzig. 1885.

fibres is possible, and under all circumstances the degenerative process already described goes on to completion. Glück, however, claims to have observed an actual union of the two ends, with re-establishment of function, at a time too early to have admitted the occurrences of degeneration and regeneration; and Wolberg, approaching the subject from the surgical side, and considering the results of nerve-suture, inclines to the same view.[1]

In the midst of such contrary statements, what conclusion can be reached as to the actual facts? It seems evident that but one conclusion is certain, viz., that under different circumstances different processes occur. The various observers are equally trustworthy. It is impossible to choose one set of conclusions rather than another, or to rely wholly upon one series of experiments, however capable the observer may be, for they all rest upon repeated observations. It is undoubtedly true that in some cases the degenerative process, so graphically pictured by Ranvier, from the beginning segmentation of the myelin down to the final result in the connective-tissue strand, the relic of the empty sheath of Schwann, does go on; while in other cases of a less serious nature the destruction is less complete, and there remains a fibre consisting of a sheath of Schwann, containing a granular mass which may be either an axis cylinder or a mass capable of developing into an axis cylinder under favorable circumstances. If this is the case, we can affirm that brilliant surgical successes, with rapid restoration of nerve function after suture, are possible when the partial degeneration is present, but are impossible when the total destruction of the nerve-fibre has occurred. And statistics show that there is a certain percentage of operations which fail of any result, though repeated on the same nerve.

It is evident that future research should be directed, not so much to determine which of the processes described occurs, as to settle under what circumstances the one is produced rather than the other. And such research will have an eminently practical bearing, inasmuch as it will also demonstrate under what circumstances nerve-suture is likely to be attended by success.

The Process of Regeneration.—After the process of degeneration has gone on for some time in the nerve-fibre, it may cease, and the process of regeneration may begin. With regard to the method of this process two widely divergent views are held. Ranvier and his followers claim that the new nerve is wholly a product of the central end of the injured nerve, growing out from it and making its way along the track of the peripheral end, which takes no active part in the process. Neumann and Mayer, on the contrary, believe that the regeneration goes on in the peripheral end of the cut nerve, segment by segment being formed successively, beginning at the point of injury and proceeding outward, the entire nerve being built up by the union of each distal segment with the one lying centrally to it, until this process has reached the end. These various views demand a more exact statement.

Ranvier describes several ways in which the new fibres issue from the central end.[2] He has seen the central end of an individual nerve-fibre become hypertrophied, and from this swollen part a single new fibre start out already medullated. He has also seen a single axis-cylinder grow out, and then divide into two, or even more, axis-cylinders, each of which develops into a complete medullated nerve; or from the swollen central end of a single fibre several medullated and segmented fibres may originate, or one medullated fibre may be sent out with several non-medullated fibres coiled about it; or, lastly, a simple axis-cylinder branches out without a medullary sheath, divides into two, and each of these in turn divides into two, and so on until the sheath of Schwann, which had originally but one axis-cylinder within it, contains as many as eight or more (Fig. 4, *a*). These new fibres appear like a brush upon the end of the divided nerve, and wind about each other, forming a sort of plexus. By the aid of the cicatricial tissue, which usually joins the central end with the degenerated peripheral end, the bushy, branching fibres are directed outward toward the periphery. And when they reach the peripheral end of the cut nerve they insinuate themselves into the old remaining sheaths of Schwann, or between those sheaths, and grow on and outward till at last they reach the termination of the peripheral end, and the regeneration is complete. The terminal plates upon the muscles are renewed by a production of protoplasm in the plate. The description given by Neumann and Mayer is very different. It will be re-

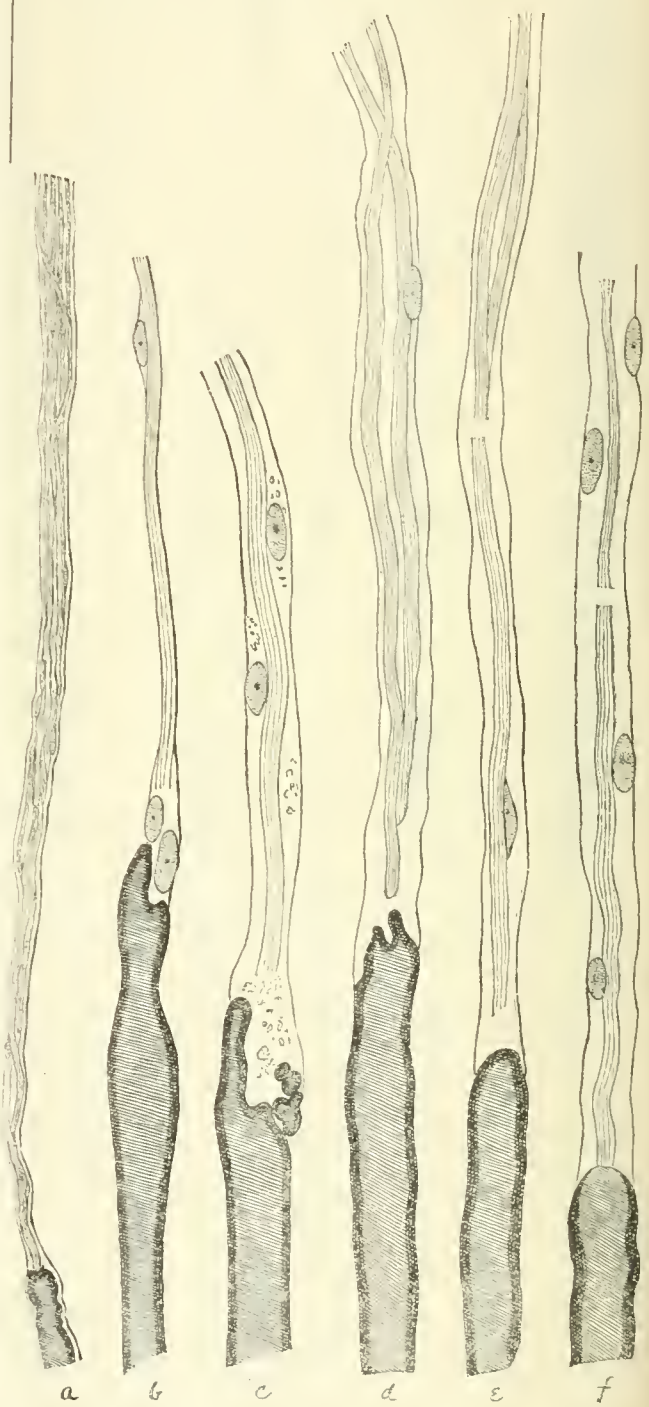

Fig. 4.—Process of Regeneration. (After Neumann.) *a*, Outgrowth of new nerve-fibre from central end, division into numerous axis-cylinders (Ranvier); *b*, development of axis-cylinder in peripheral end, the new fibre separated from the old by nuclei; *c*, ditto, with increase of protoplasm destined to become a new myelin sheath, overlapping of old myelin upon the new; *d*, two new fibres developing in a peripheral segment and ready to unite with the central end; *e*, two segments nearly developed, the central one in advance of the peripheral one; *f*, final union of the peripheral with the central segment, nuclei still remaining.

[2] L. c., ii., 42–67.

membered that they describe, as the terminal result of the process of degeneration, a band of fibres each consisting of a sheath of Schwann containing a granular mass. The process of regeneration begins in this mass. Within it they have seen a narrow band of fine homogeneous substance appear, which has the structure of a rudimentary axis-cylinder (Fig. 3, *b*). This does not fill the sheath of Schwann, and is often pressed aside by the nuclei which lie in that sheath (Fig. 4, *c*). It is not at first continuous with the end of the old axis-cylinder, remaining in the central part of the compressed or divided nerve, but as it increases in definite structure it approaches this old axis-cylinder, and finally unites with it. At the point of union a ring of Ranvier is formed. As this axis-cylinder develops, a substance is gradually formed around it, which is stained by osmic acid. This increases in thickness as the protoplasmic mass and the nuclei diminish, until it finally forms a new myelin sheath. The new myelin sheath is never continuous with the old one in the central end of the nerve, since it is separated from that by the ring of Ranvier; but often at first the older sheath seems to bulge out and encircle the new sheath, though this appearance is never permanent (Fig. 4, *c*). At the point of union of the new fibre with the old one, nuclei are often found; but these, like the others, gradually disappear (Fig. 4, *b* and *d*). Lastly, a new sheath of Schwann is produced around the new myelin sheath, and within the old sheath of Schwann. It presses aside the old sheath, together with such masses of protoplasm, drops of myelin, and nuclei as may remain, leaving them thus wholly outside of the new-made fibre, so that they coalesce with, and make part of, the endoneurium (Fig. 4, *e*). The new sheath of Schwann has but one nucleus in each segment, and presents the nodes of Ranvier at regular intervals.

Neumann has shown that this process goes on in every individual segment of the nerve-sheath, so that in segment by segment, proceeding toward the periphery, the regenerative change occurs, and as each segment approaches completion it joins itself to the preceding one (Fig. 4, *e* and *f*), until finally the entire nerve is re-established in its entire length. As the degenerative process begins in the segment nearest to the point of compression, so does the process of regeneration; and in some nerves the two processes may be seen going on together, the segments near the seat of injury being renewed while those at the periphery are still in a state of degeneration. The new fibres do not grow out from the old ones, as Ranvier describes in the regeneration of cut fibres, but protoplasm, with specific developmental properties, forms and differentiates the elements of the new fibre, and then unites it to the old one. The new fibres are, at first, somewhat smaller in calibre than the old ones (Fig. 4, *f*), but they gradually attain a normal size, and then the process may be said to be completed.

While Neumann would have the new fibres develop from the granular mass remaining in the old sheath of Schwann, Günther, Hjelt, and Weir Mitchell suppose that they may originate from the nuclei of the old sheath, or even from connective-tissue cells and neurilemma nuclei remaining in the connective-tissue strand, and to this opinion Wolberg agrees. It is evident, therefore, that the process of regeneration is by no means accurately determined. But here again it is possible that conflicting statements may be explained. The method of regeneration may, perhaps, depend upon the exact stage of degeneration reached before it begins. If the product of degeneration is a simple band of connective tissue, it seems probable that the nerve-fibre will have to grow into it from a central origin, as in its original development in fetal life, unless the connective-tissue cells recently discovered are neuro-plastic cells, and have the power of producing new nerves, just as cells of periosteum may produce a new bone. If, however, when degeneration ceases, there remains a sheath of Schwann containing a granular protoplasmic mass, it is not at all improbable that that mass may be differentiated into an axis-cylinder and a medullary sheath, and joined to the old nerve-fibre, a process which has its analogy in the medullation of nerves in the embryonal state. If we admit, with Wolberg, that in some cases the axis-cylinder is not destroyed, the formation of new myelin is a rapid matter. That some such process as the one last described must occur in certain cases is certain, when the rapid recovery after minor injuries is considered, and when the results of nerve suture are taken into account; for in both these conditions the return of function occurs long before a new nerve-fibre, starting out from the old one, could have reached the periphery.

It is affirmed by Mayer that individual nerve fibres in normal nerves are constantly undergoing these processes of degeneration and regeneration, either because the necessary renewal of worn-out tissue takes place in this manner, or because slight injuries from pressure or over-strain are sufficient to start up degeneration in single fibres.

The process of degeneration in the nerves, consequent upon the destruction of the ganglion cells from which they arise (the so-called Wallerian degeneration) differs in no respect from that ensuing upon compression or division, excepting that in the latter case only the distal part of the divided nerve undergoes the pathological change, while in the former it is the entire nerve that is affected. And in the changes described in multiple neuritis the same progress of events and the same varieties of termination are observed.

When the cases of multiple neuritis are examined from a pathological standpoint several varieties may be distinguished. In some of the cases, and these are the most numerous, there is a parenchymatous inflammation in the nerve-fibre only visible to the microscope. At the outset of this inflammation the myelin sheath appears slightly swollen, is less homogeneous, and, from a difference of refractive power, is less translucent. It then becomes split up into segments of different length and form, the segmentation occurring preferably at the incisures of Schmitt, while the incisures at other parts disappear. Between these segments of myelin, a finely granular protoplasm is seen, in which new nuclei are found. These nuclei probably are the cells of Rosenheim which have emigrated, although a few near the nucleus of the sheath of Schwann may be due to its division. In some fibres the axis cylinder may still be preserved. In others it is broken at the same places as the myelin. At the next stage of the process the changes are more marked. The myelin is now reduced to a series of small globules surrounded everywhere by granular protoplasm, and in this protoplasm the nuclei are now very numerous. The axis cylinder cannot be distinguished in the mass, as a rule, but occasionally a fine line is seen passing through the mass, which may be a remaining cylinder. The succeeding stage presents a different picture. While up to this time the size of the nerve-fibre has remained about normal and uniform, it is now seen to vary. At places the fibre is still wide and filled with a granular mass, at other places it is narrow, the mass having disappeared, leaving either a collapsed sheath or a sheath containing only nuclei here and there. In a few such narrow fibres there seems to be an axis cylinder lying directly within the sheath of Schwann, and occasionally separated from it at various places by nuclei. But this appearance is rarely seen. As a rule, no trace of the axis cylinder remains. As any single fibre may show at some places constrictions, at others dilatations, the variation in its calibre is the most striking feature of this stage. In the terminal stage the calibre is uniform again, but is now everywhere reduced. The sheath of Schwann is empty, or contains only a little granular substance, and the nuclei are now less numerous than before. There is in fact only an atrophied tube with none of its original contents. These tubes lying side by side are folded and undulating, and appear like a strand of connective tissue.

These various stages of parenchymatous inflammation are to be seen in different fibres in the same specimen. Their appearance is identical with that observed in the course of degeneration of a nerve after compression, or after destruction of the spinal ganglion-cells. This has led such an accurate observer as Erb to advance the hypothesis that some slight changes in trophic cells in the spinal cord, not visible to the microscope, are present primarily, and that these changes are of a secondary nature.[1] But this cannot be admitted. Those who would explain the parenchymatous neuritis as secondary to changes in the cord, fail to explain why it should be limited, as it is, to the distal portions of the nerves, and not be continuous through the nerve-trunks, and anterior nerve-roots into the anterior cells. They also offer no explanation for the cases in which the sensory, as well as the motor, nerves are affected, centrifugal degeneration of these nerves from spinal lesion being unknown. Strumpell, in meeting Erb's hypothesis, urges with reason that a parenchymatous neuritis has its parallel in other parenchymatous inflammations, and therefore does not need to be traced to any primary affection in trophic cells. He also mentions the existence of primary lateral sclerosis of the cord, similar in all respects to secondary degeneration of the pyramidal columns—yet now admitted to be a primary disease—as illustration of the fact that like changes are not always to be traced to one cause. It cannot but be admitted, therefore, that the first class of cases of neuritis must be considered as due to a primary parenchymatous inflammation in the nerve-fibres. This form seems to be much more frequent in its occurrence than the first variety, and constitutes the lesion in the majority of the cases hitherto reported. The appearance in section is seen in Fig. 5, *b*. The appearances of single fibres are the same as those shown in Figs. 2 and 3.

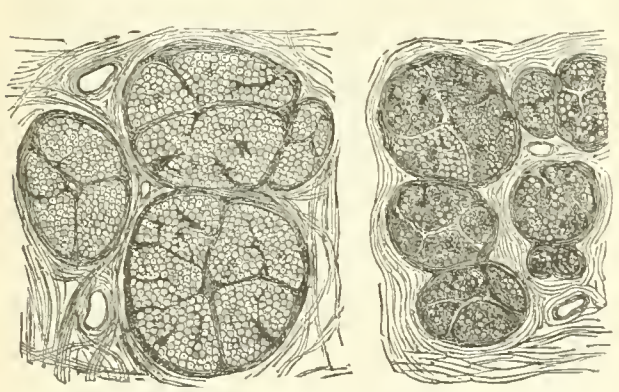

FIG. 5.—(After Joffroy.) *a*, Section through normal nerve; *b*, section through degenerated nerve in a case of multiple neuritis, bundles reduced in size, individual fibres degenerating, their place taken by débris.

A second class of cases presents a different appearance. In this class the mere inspection shows the nerve to have been the seat of pathological changes, for it is either congested, swollen, and lacking in lustre, or it is yellow and irregularly swelled by the accumulation of fat, or it is evidently reduced to a mere connective-tissue strand. Upon teasing the nerve it is at once clear, from its brittleness, that individual fibres are lacking in continuity and are changed in structure. And if it is examined under the microscope the exudation of serum and of lymphoid bodies, the great increase in the number of connective-tissue nuclei, the distended condition of the vessels, as well as the various appearances characteristic of nerve degeneration, are clearly seen. Here the inflammation is either originally an interstitial inflammation or, more probably, a diffuse one. It is possible that the degenerative processes in the nerves may have been due to the compression by the exuded products of inflammation within the nerve-sheath. In one or two cases where the patient died early in the disease, the nerve-fibres which lay near the vessels were affected to a greater degree than those lying deeper, and from this fact it was concluded that their degeneration was secondary. In other cases, however, all the fibres in a bundle are equally involved. Here it is probable that the inflammation was diffuse from the outset, parenchyma and interstitial tissue being affected simultaneously. The final result in either case is a diffuse inflammation. One marked feature in these cases is the large amount of fatty deposit found in the altered nerves. This is to be ascribed to the fact that myelin in undergoing degeneration breaks down into globules and undergoes a fatty change. It is itself allied to fat, and making up, as it does, a large part of the bulk of the fibre, it would be noticeable in the product of degeneration if it were not absorbed. In this form the absorption seems to be interfered with by the vascular condition, and hence the residual amount of fat is increased. The changes observed in the nerve-fibres are very similar to those seen in the first form of neuritis, and need not be described again.

It is to be noted that in both of these forms the pathological changes are always more intense in, and are occasionally limited to, the peripheral terminations of the nerves. The nerve-trunks may be slightly involved in their distal portions, but it is very rare to find any changes in them at their origin from the plexuses. And, as a rule, the spinal nerve-roots in cases of multiple neuritis are normal. In making autopsies upon such cases this fact is to be remembered, and the nerves are to be removed down to their finer branches in the muscles and fascia.

One additional pathological form must be mentioned, since it has been described by such a careful observer as Gombault.[1] It is the so-called segmental periaxillary neuritis. In toxic neuritis from lead-poisoning, Gombault found that the degenerative process was not uniform in the entire length of a nerve-fibre. On the contrary, entirely normal segments alternated with the degenerated segments in the nerve. Mayer has noticed a somewhat similar condition (Fig. 3, *e*). The changes already described take place in the myelin sheath of the affected segment, even to its entire absorption, leaving the axis cylinder in the sheath of Schwann. But as the adjacent segments are not involved, regeneration is thought to be more easily accomplished. Pitres and Vaillard[2] have noticed a somewhat similar condition in the neuritis occurring after diphtheria, although in their case the axis cylinder as well as the myelin sheath was totally destroyed in many segments.

While it is, of course, impossible to describe definitely the process which goes on to complete regeneration of nerves in multiple neuritis, there is no reason to suppose that it differs in any way from that observed in experimental lesions.

The time required for the completion of the process will depend upon the severity and extent of the degeneration. When that is slight the recovery may be rapid, cases having been reported where a total cure took place in two months. As a rule, however, it is a slow process. The large majority of the cases on record required over six months for the complete regeneration, and in not a few cases from ten to sixteen months elapsed before the condition of the nerves was proved to be normal by the total disappearance of all symptoms.

A degeneration of the muscles proceeds hand in hand with that of the nerves. This is usually in the form of an atrophy, with fatty degeneration and an increase of nuclei. The muscle-fibres become thin, homogeneous, are easily split up, contain fatty granules, and finally, in place of the atrophic muscle, new connective tissue is found. When no regeneration takes place, a mass of connective tissue replaces the muscle, containing a few muscular elements.

With the end of 1883 we may consider the third stage

[1] Erb: Neurol. Centralbl., 1883, p. 481.

[1] Gombault: Archives de Phys., 1873, p. 592; also Arch. de Neurol., i., 1.
[2] Pitres et Vaillard: De la Nevrite segmentaire, Arch. de Neurol., xi., 337.

of pathological discovery in the history of multiple neuritis as terminating. At that date the symptoms of the disease had been recognized as constituting a distinct clinical picture; hypothetical lesions in the spinal cord had been abandoned, and the exact pathology of the disease had been ascertained. Since 1883 the final period in the development of knowledge of the affection has been in progress. About one hundred cases, of varying degrees of severity, have been observed (see Bibliography). The lesions described have been confirmed in all their details. The symptoms arising in the course of the disease have been subjected to careful analysis, together with their varied modes of combination. Certain diseases hitherto considered of spinal origin are found to be due to peripheral disease. Thus it has been discovered that a form of ataxia may occur from multiple neuritis of alcoholic or arsenical poisoning, which closely resembles and was formerly confounded with tabes; also, that some cases supposed to be anterior poliomyelitis must now be differently named. And as physicians review their records, they find that former diagnoses require revision in the light of new discoveries, and that greater circumspection is to be exercised in differentiating spinal from peripheral affections. The grounds for such differential diagnosis will require attention in the next lecture.

And, what is perhaps of greater importance, the fact has been elicited that some combinations of symptoms formerly supposed to be without a pathological basis, some of the so-called peripheral neuroses, really belong to this class of diseases. At present we have only time to allude to one or two forms of peripheral neuroses which must be removed from that unsatisfactory category of disease and be considered as peripheral neuritis.

And the first of these is the affection termed numb-fingers. This was first described by J. J. Putnam, of Boston, but met with instant recognition from neurologists and from general practitioners all over the world. It is a disease chiefly seen in women between the ages of forty and sixty, usually associated with dyspeptic or uterine symptoms, but entirely independent of them. It begins as a tingling sensation in the ends of the fingers, felt at night, and sufficiently annoying to keep the patient awake. It then extends to the entire fingers, and may invade the hand, and is felt by day as well as by night. The fingers are so numb that all finer acts become impossible; the patient can no longer sew or knit, cannot be sure of holding anything securely, and finds herself unable to perform any delicate movement. Sometimes a slight degree of anæsthesia and analgesia can be discovered by ordinary tests, but often the disturbance of sensation is purely subjective. There is rarely any inco-ordination, and paresis is usually wanting. It may develop in the feet as well as in the hands, making walking more or less disagreeable, and adding to the discomfort of the patient. The affection is of indefinite duration; often subsiding quickly under treatment, sometimes baffling all attempts to arrest it. For a time it was considered a purely functional affection, then a spinal-cord disease;[1] but now, in the light of the parallelism between the symptoms mentioned and those which are characteristic of multiple neuritis, we cannot but consider it a slight form of this disease.

The second of the peripheral neuroses which must be referred to peripheral neuritis is intermittent paralysis. Cases of sudden paraplegia, lasting a few hours and passing off as rapidly as it appeared, have been observed too frequently to admit of any doubt. Westphal has described such a case in which no cause could be found. Gibney reported some cases presumably due to malaria. Others have thought the disease of functional character, either central or peripheral. But in the light of recent observations upon infectious cases of multiple neuritis it becomes evident that these sudden, transient paraplegiæ find their adequate explanation in such an affection.

And, lastly, there are numerous cases of indefinite nervous symptoms, pain of various kinds, formication, and odd sensations grouped under the indefinite term numbness, flashes of cold and heat accompanied by actual changes in the temperature of the part, or only by apparent vascular irregularities, slight spasms, or tremors; functional weakness, with sense of fatigue not reaching the grade of paresis, and many equally obscure manifestations of disturbed function in various parts of the body, which receive their best explanation in the theory of multiple neuritis.[1]

And since it was one of the objects of the founder of this lectureship to determine the true nature of such peripheral neuroses, it is with the greater interest that we examine the disease to which they must be assigned.

In the present stage of progress in the history of neuritis much attention is being given to the etiology of the disease. Cases which, from their causation, were formerly separated are now found to be closely allied in their pathology. Thus the forms of paralysis occurring after the ingestion of various poisons, such as arsenic, lead, bisulphide of carbon, and alcohol, are known to be due to a common pathological change. The various kinds of sensory and motor disturbance occurring as complications of the acute diseases, diphtheria, variola, typhoid and typhus fevers, and severe malarial fever, are traced to a lesion in the peripheral nerves. Tuberculosis is known to predispose to neuritis, and many cases formerly supposed, without question, to be produced by central or meningeal affections of a tubercular character are now assigned to a peripheral cause. It is a question whether syphilis will cause a simple degenerative neuritis, but syphilitic affections of the nerves are easily recognized and well known. Nor can the nervous system escape the action of those micro-organisms which are now recognized as the constant cause of many diseases. There is an epidemic form of multiple neuritis, fortunately not prevalent in this country, but occasionally imported here in the form of sporadic cases, known as kakke, or beri-beri, the bacillus of which has recently been discovered and cultivated. And, lastly, there is a class of cases, of supposed spontaneous origin, in which cold or overexertion are assigned as causes, but which need further investigation in regard to their etiology.

It is evident from this array of causes that several conditions formerly separated from one another because of the different circumstances of their occurrence are really forms of the same disease. But while they may be brought together upon a pathological basis, and while all have many symptoms in common, each of the forms of neuritis presents certain distinct features. Without dwelling too long upon any single variety, it will be necessary to review the different classes of cases in order to obtain a clinical picture of each. And such a review, together with the analysis of the symptoms of multiple neuritis, the discussion of its diagnosis from other diseases, its prognosis, and the treatment, will occupy us at the next lecture.

Heat Holidays.—In Switzerland and some parts of Germany the law provides that all schools, public or private, must give the scholars a holiday whenever the temperature reaches a certain height. The regulations in Basle are that when the temperature reaches 77° F. in the shade by 10 A.M. the school must be closed until the late afternoon. These heat holidays are very popular among the scholars.

Convulsions may be frequently cut short like magic by turning the patient on his left side. Nausea, after ether or chloroform, may generally be controlled in the same manner.—*Ex.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 5, 1887.

A LAYMAN'S VIEW OF THE WAY TO PRACTISE MEDICINE.

IT is a fundamental part of the physician's duty that he do the very best he can for every patient. Whoever fails in this is very certain not to succeed long in his profession. It is not a common complaint, therefore, that physicians are thoughtless and unreasonable in their requirements, or prescribe conditions unnecessarily rigorous. That such things do happen sometimes, however, is the opinion of an esteemed correspondent, who has evidently suffered long from medical arts and the divagation of physiological processes. He writes us: "Many physicians, from lack of consideration, worry their patients uselessly. . . . There is, I find, a tendency on the part of physicians to set their patients many ingeniously devised supplementary tasks without fairly considering whether the chances of resultant benefit may not be overbalanced by the distress which is certain to be caused. I speak from many experiences, of which I will cite one, by way of illustration. A physician, who had me on a course of medicine, and some other treatment, prescribed, in addition, a snuff, *to be used every hour*. It soon became apparent that if I went about my usual vocation the hours would often pass away and the snuff be altogether forgotten, or I would be so situated that I could not use it. I therefore found it necessary for several months—as long as the treatment lasted—to lay aside all business and recreations, and to sit idly at home, in sight of a clock, except that I went out occasionally for an hour's walk, or to see my kind physician. The depression and distress caused by this imprisonment were great. If the snuff did me any good I am not aware of it."

We may be permitted to interpose here the remark, that if our correspondent was not able to take a dose of medicine hourly, without giving up his business, and sitting down before his clock, his trouble must have been largely mental, and of the character known as enfeeblement. However, he has other things to say.

"During the last ten years I have, at intervals, been successively (not successfully) treated by a number of well-known New York physicians, seldom for less than six months at a time. Each of these physicians expressed his positive belief that he could restore me to health. No one of them produced on me the least particle of good effect. I was treated by dieting, baths of different kinds, massage, electricity, and counter-irritation, and was given bromides of potassium and strontium, pepsin, quinine, cod-liver oil, mercury, nux vomica, and many other poisons whose names I never knew, or have forgotten. Last July I came under the treatment of a physician who informed me (although these little matters had escaped the attention of my previous physicians) that my urethra was strictured; that I should be circumcised, and that certain malformations in my nasal cavities should be removed by a series of minor operations.

"He first enlarged my meatus. It healed smaller than the calibre of the urethra. Disregarding this fact, he attempted to remove the stricture by dilatation, producing no apparent effect except to tear the orifice several times, leaving it finally in irregular shape. He then cut the stricture; but his cut was a little too short. Two weeks later he gave me a cut overlapping the first one. When I was able to walk about, he gave the meatus a second cut. Next he circumcised me. My wounds are now so far healed as to make it apparent that the circumcision will require a supplementary operation, and that the orifice of the meatus, although large enough, is crooked. It is purposed to overcome this latter difficulty by cauterizing the crooked part, so that it will become sore and heal solid, and then to make a straight cut. Meanwhile the operations in the nasal cavities are under way. I could, while undergoing these operations, have gone about much as usual, had they been undertaken in the summer. *Now* they confine me pretty closely to a warm room.

"Were it not that every physician with whom I have done business has loaded his system of treatment with uselessly onerous requirements, I should feel surprised to find that my present physician—a member of the County Medical Society, and admittedly a master of both major and minor surgery—has not, apparently, even thought it worth while to consider, intelligently, whether one order of arrangement for a series of operations is better than another, but has been content to take them just as they occurred to him, without any seeming order of fitness; and that he has performed each of my three genito-urinary operations in such way that, after healing, it has received, or must receive, another cut.

"It seems as if physicians, especially those of them who practise surgery, might worthily, and even profitably, study how to avoid imposing upon their patients unnecessary burdens. I believe that my operations might have been performed in half the time, with half the pain, with half the blood, with half the trouble, and might have been completed weeks ago. Whenever I have begged my physician for a little more expedition, a little more attention to system, a little more care, he has replied that he will submit to no dictation, and calls me 'A nervous kicker.'"

Our correspondent expresses himself with feeling, and has, we fear, some ground for complaint. Without disregarding the probability of there being another side to his story, we can quite admit the justice of his plea for more consideration in the arrangements and details of a long-continued course of medical or surgical treatment.

THE USES OF ICHTHYOL IN THERAPEUTICS.

Some curiosity has been felt by physicians to know whether the remedy known as ichthyol, or sulpho-ichthyolate of soda, has any special merits, or deserves to be treated as one of the numerous proprietary drugs forced upon the market by enterprising manufacturers. It seems but fair to judge this substance upon its merits, since it was introduced by a man of unquestioned prominence and skill in dermatological science—Professor Unna—and received at his hands an apparently careful physiological study. Accounts of Unna's researches are given in the *Journal of Cutaneous and Venereal Diseases* of September, 1886. Lorenz contributed some results of his experience in the *Deutsche Medicin. Wochensch.* in 1885. Stelwagon and Piffard have written briefly upon it (*Journal of Cutaneous and Venereal Diseases*, November, 1886). So also has Dr. Gécé (*Gazette des Hôpitaux Quarterly Compendium of Medical Science*, October, 1886, p. 447). Some very successful experiences have been reported from its use in the Charité Hospital at Berlin (*Medical and Surgical Reporter*, January 8, 1887), and Dr. Joseph Zeisler writes upon it at length in the *Chicago Medical Journal* of December, 1886. Dr. Dubelir has also given the results of his use of it in several cases of rheumatism (*Rueskaya Meditsina*, August 10, 1886).

Lorenz speaks in high terms of its value in articular rheumatism, when applied externally over the affected joints. Dubelir treated eight cases with it, six being of acute and two of chronic rheumatism. He used the drug both externally and internally, and found that it relieved the pain, but not the swelling. He recommends it, therefore, only as an anodyne. Ichthyol was also given for rheumatism of all types at Charité.

In skin diseases Dr. Stelwagon found that, in a small proportion of cases of acne rosacea and acne vulgaris, the ten or twenty per cent. solution was of value. In furunculus it acted well in three cases when applied as a twenty per cent. plaster. In a fourth case it had no effect. It was of use in psoriasis, and also in a case of lupus erythematosus. In favus it did no good. In twelve cases of eczema he found positively no beneficial effect—certainly a very damaging statement. On the other hand, Zeisler, in 56 cases of eczema, found that the drug produced excellent effects in 11 cases, good effects in 27, fair in 4, negative in 1, and unknown in 13. Dr. Zeisler says, however, that he used the ichthyol combined with zinc ointment as a base, the strength being from five to thirty per cent. This seriously vitiates the value of his conclusions as to its special potency. In 11 bad cases of sycosis, epilation was practised; ichthyol soap and ten per cent. ichthyol ointment was used. The effects were excellent in 4, good in 7, cases. In acne vulgaris good results were only attained by its internal use. In acne rosacea the action was "remarkable" in two cases, and very satisfactory in five. Two chronic and very obstinate cases are reported by Dr. Zeisler, in which a ten per cent. ichthyol salve, sulphur-naphthol soap, and occasional mechanical treatment were resorted to. Dr. Zeisler seems to think that the drug has some effect in chronic rheumatism and dyspepsia.

Ichthyol mixes with all of the ointment bases, and may be made up with vaseline, cold-cream, zinc ointment, etc. It is also used in watery solution, and as a paste, or a soap. It is given internally in capsules of one to two grains, of which from three to ten may be taken daily. It does not disturb the stomach. It has a strong, peculiar odor, and leaves a brownish discoloration of the skin, which soon disappears. Unna believes that it is a strong reducing agent, drawing oxygen from the tissues. It is spoken of as having a regenerative effect in small, and a resolving action in larger, doses; it causes the blood-vessels to contract, and so possesses an astringent property.

It will be seen that the indications for the use of ichthyol are still somewhat indefinite. But while it apparently possesses no wonderful specific properties in any direction, it may be found to be worthy of a place in therapeutics.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The attendance at the State Society was fully up to the average, and, scientifically speaking, the meeting was a reasonable success. The papers were numerous and good. Many gentlemen on account of the stress of business were unable to obtain any hearing and were forced to read only by title. Much dissatisfaction was caused thereby, although perhaps the error, from a Society stand-point, was on the right side. In another place we present a full report of the proceedings, which speaks for itself.

This year the presidency belonged to New York City. The choice of Dr. A. L. Loomis was an eminently proper one, and will meet with that approval which is the reward for long and faithful labors as an instructive teacher, a lucid writer, and a successful practitioner.

THE REGULATION OF PROSTITUTION IN GREECE.

Our French contemporary, *Le Médecin Moniteur de l'Hygiène Publique*, is learned in classical medicine, and particularly in that part which relates to the cult of Venus and Priapus. In a recent issue the "monitor of public hygiene" discourses in an interesting way upon the laws of prostitution in ancient Greece. These laws, as will appear, convey a valuable lesson, for they show one way of dealing with this question which is sure to fail, because it allows license to the man and slavery to the woman, taking account of the passions only, but not of the health. The laws enacted by Solon established a class of prostitutes. These women had no rights as citizens, could not have legal offspring, were obliged to wear a certain costume, could not enter the temples, and, in fine, had no civil, social, or religious rights. The married woman, on the other hand, was destined to be a mother and to rear children. Her place was the home; she was not allowed at the theatre or public places; she was illiterate, ignorant, and had few accomplishments. To further protect her, or prevent her from indulging in intrigues, there were certain officials, called "gynèco-cosmoi," charged with spying upon her conduct. Severe punishments might be inflicted in case of adultery. The man, on the other hand, was free. "We have our courtesans," said Demosthenes, "for pleasure, our concubines (domestics) for the care of our person, our wives to give us children and rule with fidelity over our homes." This

was a very pleasant arrangement for the man, but was open to the objection from a hygienic stand-point that the man who took his pleasure with the courtesans might bring to his home physical troubles which would interfere with his domestic felicities and the propagation of healthy children. The Greek method of dealing with prostitution protected the home for a time and preserved a class of pure women in a most dissolute age. But the wife in time tired of servitude, and infidelity became common, while the courtesan took away from her more and more of her exclusive privileges. The result finally is pictured in the dialogues of Lucian and the letters of Alciphron.

THE MIDDLETON GOLDSMITH LECTURES.

It is with great gratification that we present to our readers the first of the Middleton Goldsmith lectures, delivered before the New York Pathological Society. In the movement thus auspiciously inaugurated we recognize a substantial encouragement for progressive work, and a becoming stimulus for patient original research. The New York Pathological Society is the foremost organization of its kind in the world. Its noble record is its best claim for such an honorable position. It is fortunate that its old friends have not forgotten it. Dr. Middleton Goldsmith, now of Rutland, Vt., has, with a few others, been spared to watch its success from the beginning of its existence. In fact, as one of its founders, he has noted its steady progress from a handful of earnest men to a membership of hundreds, absorbing, appropriating, and utilizing the pathological studies of every dead-house of a great city. With a liberality worthy of all praise, and under the advice of a fellow-founder and life-long friend, Dr. John C. Peters, he has endowed a lectureship which shall justly and appropriately bear his name for all time. May he be spared yet many a year to realize to still fuller fruition his cherished wishes.

News of the Week.

Homœopathy and Hypodermics.—The dean of a homœopathic medical college in this city is reported to have bought another hypodermic syringe recently. This is not what Hahnemann taught; it is not homœopathic.

The Cause of Right-Handedness, according to Dr. Oscar H. Allis, is the liver. This throws an extra weight upon the right side, and makes the right the more reliable limb. The use of the right arm, situated directly over the right leg, tends less to the disturbance of the centre of gravity than does the use of the left arm. But how will the doctor explain left-handedness?

Boldo-glucine is the name of another new hypnotic, obtained from boldo by Dr. René Juranville. It has a quieting effect in nervous insomnia, given in doses of twenty grains to two drachms.

Reforms Needed in the Naval Medical Service.—In his last annual report Surgeon-General Gunnel recommends an appropriation for the establishment of a naval hospital at Widow's Island, to receive patients from infected vessels of the North Atlantic squadron. Plans for the construction of the hospital accompany the report. The Surgeon-General states that it is impossible, with the present inducements offered, to find young medical men who are disposed to become medical officers of the navy. He recommends that the medical corps of the navy be put on an equality, both as to rank and pay, with that of the army.

Colorado and Consumption.—The Health Commissioner of Denver, Col., reports that in 1886 there were one hundred and ninety-five deaths from consumption in Denver, Col., of which only five were contracted in that place or State.

The Pasteur Institute.—The subscriptions have at last account reached the sum of $300,000.

Death from the Electric Current.—During the progress of a fire in this city, recently, Superintendent Frederick Simmons, who attempted to cut a wire of the United States Illuminating Company, which caused obstruction to the firemen, was instantly struck dead by the force of the electric current with which it was charged.

An Annex to Bellevue Hospital, for purposes of abdominal surgery, is to be erected. It will be attached to the Fourth or Non-collegiate Division.

The Trustees of the Massachusetts General Hospital have decided to build a new ward, to be devoted to abdominal surgery.

The Danger of Being a Pioneer in Oöphorectomy.—Dr. Robert Batty, now the pride of Southern medicine, says in describing the history of his first case: "While engaged in nursing assiduously, as I did my first patient, spending ten days at her bedside, without leaving the house for a moment, even for a change of linen—during this time of great suspense and anxiety, in the office of one of my brother practitioners, were held nightly meetings of the profession of the town, receiving reports on the condition of my patient, awaiting her demise with anxious longings in order to institute proceedings in our court and put me before the bar as a criminal."

Worshippers of Small-pox.—There is nothing, however monstrous or grotesque, that is deemed unfit for worship, says Mr. Saltus in his "Anatomy of Negation." In Benares there is a shrine to small-pox, in Gaya there is one to the police. Perhaps in this city there will soon be one for both.

Dr. Metcalf on the Treatment of Sciatica.—Dr. Metcalf, of this city, writes to the *Boston Medical and Surgical Journal*, that no prescription for sciatica has ever equalled in efficacy the following: ℞. Tinct. aconit. rad., tinct. colchic. sem., tinct. belladonna, āā ʒ j. M. Sig.: Dose, six drops every six hours. He also uses triturate tablets, each containing three drops of the following: Tincture of aconite-root, tincture of seeds of colchicum, tincture of belladonna, tincture of actea racemosa—equal parts by volume. Dose, one every four or eight hours.

Mitral Disease and Active Work.—The late Lord Iddesleigh had a lesion of the mitral valves for forty years, but engaged during all that time in active, intellectual, and political work. Contrary to what used to be taught, this kind of life did his heart no harm, but the lesion remained stationary.

Testimonial to Dr. N. S. Davis.—The attainment of the fiftieth year of his professional career by Dr. Davis was signalized, on January 20th, by a very cordial demonstration on the part of the students of the Chicago Medical College. A study-chair and a book-case were presented to the venerable doctor, with the accompaniment of flowers and graceful oratory. Dr. Davis is now in his seventy-ninth year.

Dr. George S. Thayer, ex-Mayor of Binghamton, died suddenly of apoplexy, recently.

Reaffirming the Constitutionality of the Law Compelling the Licensing and Registration of Physicians.—From August to December, 1886, Albert Eastman, a resident of Steuben County, Ind., practised as a physician and surgeon. He had, however, not obtained a license for his privilege, and upon an affidavit being filed against him he was tried, convicted, and fined. The conviction was made under the act of April 11, 1885, which makes it unlawful for anyone to practise without a license. Eastman at the trial made a motion to quash the indictment, on the ground that the law was unconstitutional and void, for the reason that the Legislature had no right to place restriction upon the liberty of a citizen in following any profession or vocation which he chose to. The motion was overruled, and after the conviction Eastman appealed to the Supreme Court, where the decision of the lower court was affirmed. The opinion was very comprehensive in every citation, and was written by Chief-Justice Elliott. It held that the case of admitting physicians to practise was the same as the admitting of lawyers, and that the admittees should be thoroughly proficient in learning and skill, so as to protect the interests of the State. A physician was trusted with care of the health, life, and limbs of the people of the State, and it was in order to protect such that the law of license was enacted.

Doctors and the Declaration of Independence.—Dr. S. Weir Mitchell contends that he was right in his remark that Dr. Benjamin Rush was the only physician who signed the Declaration of Independence. Josiah Bartlett, Lyman Hall, Oliver Wolcott, and Matthew Thornton all studied and practised medicine somewhat, but none were graduates or titular M.D.'s like Rush.

Restraint at the Utica Insane Asylum.—It is announced in the daily papers that the authorities of the State Lunatic Asylum at Utica have abandoned the use of mechanical restraint. This means, we presume, that the "crib" has gone forever.

Professor David Swing on "the Christian Science of Healing."—A few weeks ago, when an apostle of the new mode of medical practice had finished reading an address upon the "Christian Science of Healing," some critic said the term "science" should be omitted from such lectures; some one whispered also the word "Christian;" while near such omissions the word "healing" might well take part in the elimination, and not be left to utter solitude. . . . The "Metaphysical Cure" is destined not wholly to fail, but to become a popular element in medical practice. The public may well reject a large part of its claims, and may then thank its disciples for telling us plainly that we are sick often from weakness of will and want of enthusiasm—not real invalids, but whining hypochondriacs, who should be sawing wood in the basement or digging in the back-yard, instead of lying upon the family lounge or dealing out symptoms to the family doctor. For all such suggestions, and for accompanying proofs, these practitioners merit not the fame of discoverers, but of new and eloquent exhorters to action.

Another Successful Pneumotomy is reported by Dr. J. Thiriar, of Brussels (*Bullet. de l'Acad. Royale de Méd.*, 1886). The patient suffered from a large pulmonary cavity, due probably to a suppurating interlobar pleurisy. It had opened into a bronchus.

Regulating Prostitution.—Fournier asked 873 male syphilitics how they had become infected. It was found that 625 got the disease from registered, licensed, and regularly examined prostitutes, 100 from working-women, 24 from domestics, 24 from married women, 46 from clandestine prostitutes. The inquiry showed that the licensed prostitute was the most serious source of infection.

The Faculty of Medicine of Paris has conferred the Lacaze Prize of 10,000 fr., awarded every four years for the best work on the treatment of fevers, typhoid in particular, to M. Albert Robin, for his "Leçons de Clinique et de Thérapeutique Médicales."

Medical Students in the German Universities.—The total number of students in the medical faculties of the German universities is about three hundred in excess of what it was last winter session, the largest increase (seventy-six) being at Würzburg. Berlin shows a decrease of eight, and Königsberg a decrease of four.

Charity Organization.—We are glad to notice, from the reports made at the recent annual meeting, that this society continues to flourish and extend its work. It has done good work in the cause of medical charity, by demonstrating that in the dispensaries examined one-third of the patients can afford to pay, and one-third give a wrong address and are more or less frauds.

The Dangers of a Milk Diet.—That milk is not always a good thing for adults is well known; but it seems that an exclusive milk diet may even bring on dilatation of the stomach, emaciation, and many other distressing symptoms. A patient illustrating this fact was recently shown by M. Debove at the Société Médicale des Hôpitaux. The man had had alcoholic gastritis, and lost thirty-six pounds under a milk diet.

Pulsatilla in Acute Orchitis.—Dr. Gerard Smith writes (*British Medical Journal*) in the following enthusiastic strain about pulsatilla: "Having witnessed the striking curative action of pulsatilla in acute orchitis and epididymitis, I should like to persuade others to follow Dr. Brunton's advice, and give this drug in inflammatory states of the testicle, epididymis, and spermatic cord. To have it in our power to subdue promptly the intense suffering of such cases is a great blessing; and the relief is so rapid that it is even unnecessary to employ morphine to subdue the pain, while the swelling and heat subside more rapidly than under any other drug."

A Too Healthy City.—St. Paul, Minn., reports for the year 1886 the very extraordinary death-rate of 12 per 1,000

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-first Annual Meeting, held in Albany, February 1, 2, and 3, 1887.

TUESDAY, FEBRUARY 1ST—FIRST DAY—MORNING SESSION.

THE Society convened in the Court-room in the City Hall, and was called to order at ten o'clock by the President, DR. WILLIAM S. ELY, of Rochester.

Prayer was offered by REV. W. W. FOSTER, Jr.

THE PRESIDENT then delivered his inaugural address, after which he appointed the following committees:

Business Committee—Drs. F. A. Castle and Laurence Johnson, of New York; and Archibald Dann, of Rochester.

Committee on Credentials—Wm. C. Bailey, Orleans County; James D. Spencer, Jefferson County; and James Macfie, Franklin County.

THE PRESIDENT'S INAUGURAL ADDRESS.

After returning his thanks for the honor of being called upon to preside over the deliberations of this body, with reference to the scientific work, he recommended that the President be given discretionary power, when the amount of scientific material will justify, to arrange for the formation of two or more sections, for which he may appoint a chairman and secretary.

He recommended also that matters pertaining to change in the existing medical laws be referred to the Committee on Legislation, with instruction that it report next year what changes are required in the laws affecting the State and County Medical Societies.

The President also recommended that the laws relating to the formation of Boards of Health be referred to the Committee on Hygiene for report next year as to the expediency of recommending any change in the present law.

Reference was made to deceased members, and the recommendation made that the page in the "Transactions" immediately preceding the obituary sketches be made a page "In Memoriam," upon which the names of deceased members during the year should be inscribed.

INVITED GUESTS.

Drs. E. W. Mulligan and H. S. Beahan, of Monroe County; R. J. Wilding, of Malone; J. E. Janvrin, of New York; Geo. H. Oliver, Dickinson, Franklin County; T. A. Foster, Portland, Me.; J. W. M. Shattuck, D. H. Cook, R. D. Clark, S. R. Morrow, E. A. Bartlett, and Franklin Townsend, of Albany; C. N. Dixon Jones, of Brooklyn; Claude Wilson, of Waterville; J. A. Morris of Hudson; G. P. English, of Booneville; G. A. Menzie, Verona; F. N. Otis, New York; Roswell Park, Buffalo; H. T. Dana, Cortland; Reuben Jeffrey, Jr., Norwich; J. H. Moon, Otsego County; S. S. Wallian, Essex County; A. M. Larkin, St. Lawrence; J. B. Ramsay, Clinton County.

The question of the appointment by the President of

A MEMBER OF THE COMMITTEE ON LEGISLATION

was raised, and on motion it was referred to the Committee on By-Laws for report as to whether, a vacancy occurring, it can be filled by appointment or must be filled by election by the Society.

THE COMMITTEE ON EXPERIMENTAL MEDICINE

reported that no bill conflicting with its interests had been introduced into the Legislature within the last year.

On motion by DR. PIFFARD, of New York, the usual

COMMITTEE ON THE PRESIDENT'S ADDRESS

was appointed, consisting of Drs. Piffard, of New York; Sherman, of St. Lawrence; and J. V. Kendall, of Onondaga County.

Several

PERMANENT MEMBERS

were then elected, in conformity with the resolution adopted last year.

DR. W. C. WEY, of Elmira, read a paper on

SEPARATION BY VIOLENCE OF THE EPIPHYSIS, AT THE HEAD OF THE HUMERUS, IN AN INFANT TWO WEEKS OLD.

He had been able to find record of only a single case, that reported by Hamilton in his work on "Fractures." The case illustrated how promptly, completely, and rapidly recovery takes place when left to nature.

DR. DAVID WEBSTER, of New York, read a paper entitled

ADAPTATION OF CORNING'S METHOD OF PRODUCING LOCAL ANÆSTHESIA TO OPERATIONS ON THE EYELIDS,

consisting of multiple puncture and the introduction of cocaine by the aid of a galvanic battery.

DR. SHERWELL, of Brooklyn, had always liked the instrument, because it was his own invention.

DR. POOLEY, of New York, had used what was more satisfactory to him than Dr. Corning's method, namely, the use of Knapp's entropion forceps, and the hypodermatic use of the cocaine.

DR. CORNING took some exception to the purpose for which Dr. Pooley had said that he applied the forceps-clamp.

DR. POOLEY replied that what he had stated was substantially what he stated in the New York Ophthalmological Society, and that he had not claimed any priority.

DR. J. LEONARD CORNING, of New York, then read a paper on his method of

MEDICATION OF THE NERVES OF THE SPINAL CORD,

which consisted in first introducing cocaine by means of the electro-chemical method or by means of the hypodermic syringe and then covering the area with fine wire gauze and making moderate pressure, which includes the fine capillaries, without pressing out the anæsthetic.

DR. F. W. RING, of New York, testified to the practical efficacy of the method, but urged the following cautions: 1, The positive electrode must be directly over the cocaine; 2, anæsthesia is confined to the area of punctures, and therefore care must be taken not to cut outside of this limit; 3, the possibility of coagulating the vitreous; 4, a fresh solution must be used to avoid irritation.

DR. PHELPS, of Chateaugay, regarded cocaine as one of the most dangerous drugs when handled indiscriminately, and thought that it should be used in as small quantity as possible.

DR. ROOSA, of New York, thought that the dangers from the use of cocaine had been extremely exaggerated.

IS THE DANGER FROM POST-PARTUM HEMORRHAGE INCREASED BY THE USE OF ANÆSTHETICS DURING PARTURITION?

DR. FORDYCE BARKER, of New York, read a paper on the above subject, in which he said that the affirmative answer to this question was one of the most effective arguments urged against the use of anæsthetics in midwifery nearly forty years ago by such eminent obstetricians as Tyler Smith, Robert Barnes, and many others. Even the most recent authors, and many writers in medical journals, refer to the danger of anæsthetics in causing post-partum hemorrhage.

The real question is whether anæsthetics, properly administered, should be withheld from a woman in labor,

when desirable to save her from unnecessary suffering, because of the danger of causing post-partum hemorrhage.

He regards chloroform as the safest and best anæsthetic in obsetrics, and since 1850 he has not used ether.

What is termed uterine inertia is often but another name for uterine exhaustion, and this most certainly must be less likely to occur when the nerve-force and vital powers have been saved by the use of an anæsthetic. This uterine exhaustion may be and often is the result of prolonged labor, and while he was convinced that the effect of chloroform was often to prolong labor, he had not been satisfied that this apparent objection was not more than counterbalanced by the advantage obtained by its use, even where the use of the forceps has been made necessary for that cause. But in a large majority of patients his experience led him to believe that the use of chloroform shortens labor.

Dr. Barker does not hesitate to give chloroform to a woman with heart disease. In his private practice he had never had but one case of post-partum hemorrhage, and in that no anæsthetic was administered.

Dr. T. Addis Emmet, of New York, said that anæsthetics hasten labor, but that in many cases injury was done by their too early use.

Dr. W. W. Hewlett, of Suffolk County, thought that, when improperly used, chloroform might have something to do with favoring the occurrence of post-partum hemorrhage, but properly administered in the second stage it hastens labor, and he was not afraid to use it, and rarely attended a case of labor without it.

Dr. S. B. Ward, of Albany, does not regard chloroform as the safest anæsthetic in labor; but was perhaps prejudiced against it, because of its danger in general surgery. He preferred ether, and believed that the danger from the anæsthetic was much less than the danger from the severe suffering during labor without it.

Dr. McLaury, of New York, spoke in commendation of the use of chloroform. He had used hydrate of chloral with good effect.

Dr. F. A. Castle, of New York, spoke of a case in which the woman had had repeated post-partum hemorrhage, but in her eighth labor, without chloroform, the hemorrhage was so profuse that he should in her next confinement give chloroform at the closing of the second stage to give relief from the pain attending the passage of the head over the perineum.

Dr. J. O. Roe, of Rochester, read a paper on

CORRECTION OF THE DEFORMITY OF PUG-NOSE BY OPERATION,

which consists of removing from the end of the nose a sufficient portion to make it symmetrical from one end to the other. He had performed it in five cases successfully.

SPECIAL REPORT OF THE COMMITTEE ON BY-LAWS,

by Dr. W. C. Wey, of Elmira. The Committee most respectfully reported that, while it was clear that the presiding officer had no authority to fill a vacancy in a standing committee, they recommended that the action of the President in appointing Dr. Bendell a member of the Committee on Legislation be confirmed by the Society, but that it could not be taken as a precedent for similar action in the future.

The Society then adjourned, to meet at 2.30 P.M.

Afternoon Session.

The Society was called to order by The President.

THE REPORT OF THE COMMITTEE ON LEGISLATION

was read by Dr. Bendell, of Albany, which included an approval of the Purrington bill for codifying the medical laws of the State from 1806; also recommending that $100 be appropriated for Mr. Purrington for aid rendered to the Committee.

The report was adopted after discussion by Drs. Lewis, of New York; and Furbeck, of Gloversville.

Dr. Roosa, of New York, offered the following, which was unanimously adopted:

Resolved, That while the Medical Society of the State of New York approves of the report recommending the codifying of the laws of the State of New York as regards medical matters, it does not relinquish its conviction, so often expressed, that it is necessary for the interest of the people and the profession that a law creating a board of medical examiners be passed.

In connection with this subject the Secretary read a communication received from Dr. Martindale, of the Richmond County Medical Society.

Dr. H. G. Piffard, of New York, read the

REPORT OF THE COMMITTEE ON THE PRESIDENT'S ADDRESS,

which approved of recommendations one, three, and four, but regarded the second recommendation as being premature.

Dr. Sidney Ringer, of London, England, sent a paper on

THE INFLUENCE OF SMALL DOSES OF THE SALTS OF SODIUM CALCIUM AND POTASSIUM ON THE HEART AND THE SKELETAL MUSCLES OF THE TORTOISE,

which was read by Dr. E. V. Stoddard, of Rochester.

Dr. O. D. Pomeroy, of New York, read a paper in which he related

CASES EXHIBITING THE RESULTS OF MULTIPLE PARACENTESIS ON THE HEARING IN CHRONIC AURAL CATARRH.

The number of cases was twenty-four; six of which were contributed by Dr. N. J. Hepburn, of New York. There was a decided improvement in the hearing in both ears in *seven* cases; considerable gain in one ear in *three* cases; great improvement after inflation in *one*, but not maintained until puncture. In the other cases the benefit was variable.

The paper was discussed by Dr. Roosa, of New York, who regarded ordinary conversation as the best test of hearing, and he had heard with great satisfaction of one case where ordinary conversation was heard very well where previously it was heard badly. The discussion was continued by Dr. Bendell, of Albany; and Dr. Hepburn, of New York.

The President then announced the following:

COMMITTEE ON NOMINATIONS.

First District—Thomas R. Pooley, of New York.
Second District—A. M. Campbell, of Westchester.
Third District—B. A. Mynderse, of Schenectady.
Fourth District—A. W. Suitor, of Herkimer.
Fifth District—W. E. Ford, of Utica.
Sixth District—Henry C. May, of Corning.
Seventh District—J. V. Kendall, of Baldwinsville.
Eighth District—David Little, of Rochester.

The President appointed as member of this Committee from the Society at large, Dr. Harvey Jewett, of Canandaigua.

Dr. David Little, of Rochester, read a paper entitled,

IS MODERN MIDWIFERY MEDDLESOME?

In normal labor, as recommended to be practised by use of the vaginal douche, treatment of the perineum, etc., the answer was substantially in the affirmative.

Dr. Fordyce Barker, of New York, opened the discussion, and mentioned the fact that he had never had but one case in which it was necessary to suture a lacerated perineum. He recommended several years ago the use of the vaginal antiseptic douche after delivery of the placenta, to be continued three or four days, but for over

four years he has not used them unless there was some special indication.

Dr. L. Johnson, of New York, believed that a great deal of trouble in midwifery practice was due to the indiscriminate use of anæsthetics.

Dr. E. L. Partridge, of New York, spoke of the uselessness of cocaine in labor.

Dr. A. G. Gerster, of New York, spoke of the necessity of absolute cleanliness, especially as to the hands.

Dr. Barker doubted whether physiological cleanliness was the same as physical cleanliness, although he agreed with Dr. Gerster with reference to cleanliness of the hands.

Dr. J. S. Wight, of Brooklyn, reported

A CASE OF DISLOCATION OF THE LEFT FEMUR UNDER THE PUBIC ARCH.

It was first reduced into the thyroid foramen, and then reduced as if originally of that variety of dislocation.

Dr. L. Emmett Holt, of New York, then read a paper entitled

A PLEA FOR MORE CAREFUL INVESTIGATION OF THE URINE IN INFANTS AND YOUNG CHILDREN.

Primary disease of the kidneys in infancy occurs, and may not manifest itself by symptoms other than those exhibited by examination of the urine.

The paper was discussed by Dr. A. B. Simmons, of Utica, Dr. Low, of Oswego, and Dr. Kretschmar, of Brooklyn; and the discussion was closed by Dr. Holt.

Dr. F. N. Otis, of New York, read a paper on

THE TREATMENT OF DEEP URETHRAL STRICTURE,

in which he said that the central point in the paper was the recognition of strictures in the bulbous portion of the urethra *without entering the bladder*, and dividing them with a *miniature* Maisonneuve instrument (other instruments, if necessary), thus avoiding the necessity of external urethrotomy.

The Society then adjourned to meet at 7.45 P.M.

Evening Session.

The Society was called to order at 7.45 by The President.

Dr. Alfred Mercer, of Syracuse, read a paper

CONCERNING STATE PREVENTIVE MEDICINE,

the object being to stimulate an increased interest in sanitary questions through the medical and lay press.

Dr. David Little, of Rochester, exhibited a rubber bag, with tube attached, to be used as

A SUBSTITUTE FOR THE ORDINARY "DINNER-PAD,"

in applying Sayre's plaster-of-Paris jacket.

Dr. H. R. Hopkins, of Buffalo, read a paper on

THE INTOXICANT HABIT,

alcoholic, cocainic, and otherwise. Are we responsible in any degree for its causation? When is it a vice? When is it a symptom? With what diseased conditions is it associated? To what diseased conditions does it tend? What relation has the intoxicant habit to personal responsibility, liberty, and testamentary capacity? The paper was discussed by Dr. W. C. Wey, of Elmira, and Dr. W. E. Ford, of Utica.

Dr. Thomas Addis Emmet, of New York, made some

REMARKS ON INTRA-UTERINE MEDICATION.

He was the first to oppose this method of treatment. The answer to the question turns on the general pathology of uterine disease apart from diseases the result of parturition. Many of the conditions which we treat today as diseases are merely symptoms. Ordinary discharges from the uterus are due to some cause outside of the organ, the discharge being accidental. Leucorrhœa occurs from anæmia, and from local pelvic peritonitis, etc., and, therefore, treatment should be directed toward these pathological changes rather than to the symptoms produced by them.

Dr. Wylie, of New York, argued in favor of intra-uterine medication, believing that there were some conditions which could not be removed by any other mode of treatment. It should never be resorted to so long as there is peri-uterine inflammation.

Dr. A. Vander Veer, of Albany, read a paper on

THE NECESSITY FOR COMPLETE REMOVAL OF THE UTERINE APPENDAGES WHENEVER OPERATION IS CALLED FOR.

The subject was considered under two heads: (1) What proportion of cases of hystero-epilepsy are relieved by removal of the uterine appendages? (2) What condition of the tubes have been observed after simple removal of the ovaries, or Battey's operation?

Dr. S. B. Ward, of Albany, read a paper on the same subject, received from Mr. Lawson Tait, of Birmingham, England, in which he foreshadowed his probable opinion that, where operation is demanded by the presence of serious disease, even if on one side only, total removal of the uterine appendages should be practised.

Dr. T. A. Emmet believed that the operation should *never* be performed for the relief of neuralgia due to anæmia. It is still a question as to how much influence removal of the uterine appendages has upon the growth of uterine fibroids. The operation has a place, but it has been greatly abused; abused more in this country than abroad. Beyond question we owe a great deal to Mr. Tait, but if all the cases of what Dr. Emmet called peri-uterine inflammation were due to diseased ovaries and tubes, the operation had a very limited field, for he believed such patients could be cured by other means.

Dr. W. Gill Wylie, of New York, said that in cases of well marked hystero-epilepsy he would favor the operation, although his experience was by no means perfectly satisfactory. He was not prepared to remove the ovaries which were not diseased. He does not believe in removing the ovaries and tubes simply because they are diseased, but if they give rise to repeated attacks of peritonitis, and the patient is practically bedridden, or has reached an age after which her ovaries will not be of service, he would operate.

INVITED GUESTS.

Dr. Wilcox, from the Berkshire District Medical Association, Massachusetts; Pascal M. Dowd, Oswego; J. O'Dwyer, of New York; May Owen, Richmond County; J. Myers, of Kingston; J. H. Bogart, of Roslyn; S. R. A. Dolley, of Rochester; O. D. Ball, J. Lewi, John Thompson, L. B. Winne, G. L. Munson, P. J. Keegan, Joseph Craig, Thomas Trego, A. E. Larkin, George C. Culver, A. H. Hoadley, Lorenzo Hale, H. E. Mereness, J. H. Van Rensselaer, and Dr. Murphy, of Albany; F. H. Bosworth, of New York, and C. P. Byington, of Croton Landing.

The Society then adjourned to meet at 9 A.M., Wednesday.

Wednesday, February 3d—Second Day—Morning Session.

The Society was called to order by the President, Dr. Ely, of Rochester.

Prayer was offered by Rev. C. H. W. Stocking, D.D.

Dr. Chas. H. Porter, of Albany, Treasurer, presented

THE TREASURER'S REPORT,

which was referred to an Auditing Committee, consisting of Drs. B. F. Sherman, of St. Lawrence County; J. V. Kendall, of Onondaga County; and S. Sherwell, of Kings County.

Dr. W. C. Wey, of Elmira, Chairman of

THE COMMITTEE ON BY-LAWS,

asked that the question of delegateship from the Northern Medical Association be further referred to the Committee for report next year. Granted.

Dr. E. H. Parker, of Poughkeepsie, introduced a resolution concerning

THE RELATION OF COUNTY SOCIETIES TO THIS SOCIETY,

which was referred to the Committee on Legislation for report next year.

Dr. S. B. Ward, of Albany, reported the following as

INVITED GUESTS:

Drs. George Huntington and C. L. Fletcher, of Dutchess County; S. S. Richards, of Frankfort; M. B. Bagley, of Haverstraw; S. A. Russell, H. S. Case, and J. B. Southworth, of Albany; J. W. Poucher, of Gardner.

Dr. E. V. Stoddard, of Rochester, Chairman of

THE COMMITTEE ON HYGIENE,

made the annual report, which was referred to the Committee on Publication.

Dr. A. G. Gerster, of New York, read a communication on

ANTISEPTICS IN PRIVATE PRACTICE AND EMERGENCIES.

Practical demonstration of the same was made by Dr. Gerster at the hospital in the afternoon.

Dr. A. M. Phelps, of Chateaugay, demonstrated his method of

MANAGEMENT OF CERTAIN FORMS OF EQUINO-VARUS.

His view concerning the pathology of club-foot is that the deformity is primarily due to contraction of the soft parts, and secondarily to changes in the bones, which yield to the contraction. The application of a water-glass shoe was an essential feature, adjusted by the assistance of mechanical apparatus for putting the foot into the proper position.

Dr. Lucien Howe, of Buffalo, read a paper on

ANTISEPTICS,

in which he spoke of the tests, the limitations of the term, the methods required to establish the value of such an agent, the method of obtaining a pure culture, microphotographic apparatus, and the effect on the eyes of the rabbit when the culture is sterilized and when not sterilized.

The paper was discussed by Dr. Hailes, of Albany.

Dr. R. F. Weir, of New York, then read a paper on

THE TREATMENT OF REDUCIBLE AND IRREDUCIBLE HERNIA BY HEATON'S METHOD, AND BY THE RADICAL OPERATION OF TYING-OFF BY TUCKING UP THE SAC AND HIGH SUTURING OF THE INGUINAL CANAL.

The details of these methods were described. Heaton's method is applicable only to the small reducible hernias which have a distinct canal, and especially in children where trusses have failed to cure.

The radical operation is applicable to the large hernias, the irreducible hernias, in which the internal and external rings are opposite to each other, etc. According to his experience relapses occur in thirty-nine per cent., and the mortality which he had found in 425 cases was 2.85 per cent.

Dr. Charles D. Jones, of Brooklyn, described

A MODIFICATION OF MACEWEN'S METHOD

of treatment of hernia described by Dr. Weir.

Dr. Roswell Park, of Buffalo, had been so satisfied with Czerny's method that he had not resorted to any other. So far as he knew there had been no relapses.

Dr. A. Vander Veer, of Albany, said that, in the midst of all the operations that have been devised, something more is still required, in view of the success that has been obtained. Cases treated by Heaton's method have given fairly satisfactory results. In cases in which omentum complicates, the proper way to deal with it is, as Dr. Weir has said, to remove it, otherwise trouble will ensue. He uses catgut with considerable reluctance. MacEwen's is a form of one of Wood's methods.

Dr. Wylie, of New York, said that hernia after laparotomy could be prevented by drawing up the strong fascia and suturing the fascia of one side to that of the other; in that way a strong wall can be obtained.

Dr. W. B. De Garmo, of New York, did not believe that Heaton's method was adaptable to all cases, and said that in all old and more serious cases the method which

Dr. S. Van Etten, of Port Jervis, Vice-President, in the Chair.

Dr. Martindale, of Richmond County, read an abstract of a paper, in which he related a case of

THROMBOSIS OF THE RIGHT RADIAL ARTERY COMPLICATING ENDOCARDITIS,

occurring in a patient considerably beyond the middle period of life.

Dr. W. Gill Wylie, of New York, read a paper entitled

PRACTICAL OBSERVATIONS IN ABDOMINAL SURGERY.

1. The use of hot water within the peritoneal cavity after laparotomy, for the purpose of preventing shock.

2. The use of laxatives and enemas after laparotomy and in septic peritonitis.

3. The abuse of tapping abdominal tumors.

He gave a synopsis of one hundred and twenty-five cases of laparotomy.

INVITED GUESTS.

Drs. W. H. Murray, G. L. Ullman, W. J. Nellis, and R. N. Steenberg, of Albany; C. B. Herrick, of Troy; F. L. Classen, F. D. Morrill, Henry Hun, and J. F. Barker, of Albany; C. W. Wilbur, of Rochester; D. W. Houston, of Cohoes; E. H. Howard, of Monroe County; J. S. generally believed.

Dr. Roosa, of New York, believed that, at this juncture in the general discussion of this subject by the profession, all might admit and believe that there was a large number of cases of amblyopia from the combined influence of alcohol and tobacco, perhaps from the influence of tobacco alone, but he thought that we were not yet permitted to say that its occurrence from the influence of tobacco alone had been proved.

Dr. Alfred L. Loomis, of New York, then read a paper on

PAROXYSMAL CARDIAC DYSPNŒA.

In many cases of cardiac hypertrophy and dilatation dyspnœa is a prominent symptom. It is often of gradual development, and depends rather upon secondary pulmonary and renal changes than upon the cardiac lesion.

In the cases of which he wished to speak, the dyspnœa is due to influences existing within the heart. Its one essential cause is a temporary or permanent arrest of the blood within the heart and pulmonary arteries, which is either paroxysmal or it will speedily terminate in death. He related illustrative and typical cases. The primary cause is gradual failure of organic power of the heart, and the exciting cause is anything which will lead to undue cardiac action. The symptoms consist in the sudden development of dyspnœa, with pale countenance, feeble pulse, intermittent and irregular cardiac action, cold sweat, sense of extreme distress in the chest. Cardiac murmurs are not present; cardiac impulse is feeble; no evidence of valvular insufficiency; urine negative; and entire absence of pulmonary disease. Degeneration and thinning of the cardiac walls has been the most constant lesion; first, and most advanced, in the right ventricle. The essential feature of treatment consisted in regulation of diet, and a careful regulation of

exercise in the open air. Medicinally, alkalies, preparations of iron combined with small doses of digitalis.

The paper was discussed by Dr. Sherman, of Ogdensburg.

THE CLINICAL SIGNIFICANCE OF ENDOCARDIAL MURMURS.

Dr. Wesley M. Carpenter read a paper on the above subject, in which he expressed the belief that the *pathological* significance had overshadowed the *clinical* significance of endocardial murmurs, and therefore the terms "endocardial murmur" and "valvular disease of the heart" had been very frequently used synonymously.

The interest in the paper centred in the following propositions and conclusions:

Dr. J. S. Wight, of Brooklyn, reported

A CASE OF DISLOCATION OF THE LEFT FEMUR UNDER THE PUBIC ARCH.

It was first reduced into the thyroid foramen, and then reduced as if originally of that variety of dislocation.

Dr. L. Emmett Holt, of New York, then read a paper entitled

A PLEA FOR MORE CAREFUL INVESTIGATION OF THE URINE IN INFANTS AND YOUNG CHILDREN.

Primary disease of the kidneys in infancy occurs, and may not manifest itself by symptoms other than those exhibited by examination of the urine.

The paper was discussed by Dr. A. B. Simmons, of Utica, Dr. Low, of Oswego, and Dr. Kretschmar, of Brooklyn; and the discussion was closed by Dr. Holt.

Dr. F. N. Otis, of New York, read a paper on

THE TREATMENT OF DEEP URETHRAL STRICTURE,

in which he said that the central point in the paper was the recognition of strictures in the bulbous portion of the urethra *without entering the bladder*, and dividing them with a *miniature* Maisonneuve instrument (other instruments, if necessary), thus avoiding the necessity of external urethrotomy.

The Society then adjourned to meet at 7.45 P.M.

The paper was discussed by Dr. Loomis, of New York, who said that, up to the time when evidence of degeneration of the cardiac walls could be obtained, he did not mention the fact of the presence of a cardiac murmur, but when such evidence existed he informed his patient of the exact condition present. A prolongation of life depends largely on the proper management of the case with reference to hygienic measures and general medicinal treatment.

Dr. J. O'Dwyer, of New York, then demonstrated on the cadaver his method of

INTUBATION OF THE LARYNX.

He received a vote of thanks.

The Society then adjourned to meet at 2.30 P.M.

AFTERNOON SESSION.

The Society was called to order by the President at 2:45 o'clock.

AMENDMENTS TO THE BY-LAWS.

Dr. W. C. Wey, of Elmira, Chairman of the Committee, reported, recommending that delegates be elected for three instead of four years, and that they be made eligible to permanent membership after *two* years of actual service.

The recommendations were adopted and the By-laws amended to correspond with them.

THE AUDITING COMMITTEE.

Dr. Sherman, Chairman, reported that it had examined the Treasurer's report and the vouchers, and had found them in every respect correct.

The report was accepted and ordered entered upon the minutes.

Dr. E. F. Brush, of Mount Vernon, read a paper on

THE MAMMARY GLAND.

After a humorous introduction, in which he quoted instances of the secretion of milk in the mammary glands of the unimpregnated female as well as in the male, and deplored the fact that the product of human female mammary glands was threatened with competition not only by the baby-food men, but also by the male wet-nurses of the future, Dr. Brush gave his own experience with cases of mammary abscess. He pointed out that, as there is an excessive activity in the gland during the puerperal state, disturbances in the other parts of the economy produce pathological changes in it; that a malarial chill, rheumatic seizure, or the like, were often at the bottom of these troubles, and that by treating these constitutional symptoms the local manifestations could be aborted, and that this, indeed, was the rationale of the exhibition of quinine and salicylic acid in cases of abscess. For sore nipples he proposed a new, and according to his statement, an effectual, method of preventing and remedying this troublesome annoyance; for painful abscesses he recommended ice-bags, and, if necessary, strapping and bandaging, and in galactorrhœa ergot, quinine, and iodide of potassium. For emptying the breast he preferred the use of hot bottles as more efficient and gentle than breast-pumps, many of which he described as simply barbarous. He alluded to the fact that in the human female pus never exudes from the nipple, while in the bovine female it always exudes from the teats.

Dr. George F. Shrady, of New York, Chairman of the Committee, reported on

THE MERRIT H. CASH PRIZE.

The prize was awarded to an essay bearing the title "Physiological Condition and Sanitary Requirements of School Life and School-houses," bearing the motto "*Experte Crede.*"

The name of the successful competitor was Dr. A. N. Bell, of Brooklyn.

The number of essays submitted was eight.

Dr. W. E. Ford, of Utica, read a paper entitled

OBSERVATIONS ON THE REFLEX NERVOUS DISTURBANCES.

Dr. Roswell Park, of Buffalo, read a paper on

SURGERY OF THE LUNGS,

in which he gave an historical sketch, and then spoke of the indications for pneumotomy and its results, pneumectomy, experimental and clinical, and indications for its performance, and thoracoplasty, Estlander's operation and its modifications, and the general principles upon which it is based. He then reported cases which had been under his own observation.

The paper was discussed by Dr. Weir, of New York, who believed that cutting into the lung for acute abscesses did not have a firm footing in surgery; while for certain chronic conditions, such as gangrene, removal of foreign bodies, etc., it was a legitimate procedure, and one that was well established in surgery. With regard to removal of a portion of the chest-walls for the benefit of pleural and pulmonary conditions, successful results were more easily obtained.

Dr. C. C. Rice, of New York, read a paper on

THE RELATION OF LARYNGEAL TO PULMONARY PHTHISIS AND THE IMPORTANCE OF LOCAL TREATMENT,

in which he discussed the question of primary and secondary development of the laryngeal affection, also the question, Is laryngeal phthisis always tubercular? etc. He does not believe that laryngeal phthisis is always laryngeal tuberculosis, and for these cases he bespoke the benefit which comes from local treatment.

The paper was discussed by Dr. F. H. Bosworth, of New York, who substantiated the belief that laryngeal phthisis is frequently non-tubercular and susceptible of cure, and by Dr. O. B. Douglas, of New York, who

spoke of the marked benefit that followed the internal use of terebene in six-drop doses three times a day.

INVITED GUESTS.

Dr. W. E. Ford reported the following: Drs. C. S. Parkhill, of Hornellsville, and R. F. Parkhill, of Howard.

Dr. A. W. Suiter, of Herkimer, read a paper in which he gave

SOME POINTS OF MEDICO-LEGAL INTEREST IN THE SCIENTIFIC INVESTIGATION OF THE CASE OF THE PEOPLE *vs.* ROXALANA DRUSE, TOGETHER WITH AN EXHIBITION OF SPECIMENS REPRESENTING THE CORPUS DELICTI.

The paper was discussed by Dr. W. M. Carpenter, of New York, who referred to the possibility of cremation being made available for removing medico-legal evidence.

Dr. Sherman, of Ogdensburg, wished to thank the author personally for the care with which the case was worked up.

Dr. E. L. Partridge, of New York, read a paper on

INTUBATION OF THE LARYNX,

in which he spoke of the dangers of the operation, the fact that it did not compete with tracheotomy, and he believed that it should be tried carefully and industriously, and that the credit of the method should be given to O'Dwyer, an American investigator.

Dr. A. Jacobi, of New York, said that he felt obliged and was willing and anxious to discard the opinion he entertained two years ago, and which he published in "Pepper's System of Medicine," with reference to intubation of the larynx, and wished to say that if anyone deserved credit for his discovery and his painstaking labor, it certainly was Dr. O'Dwyer. There was no doubt that a large number of children had been relieved immediately, not only temporarily, but permanently.

Dr. Hopkins, of Buffalo, referred to six cases in which impending death was overcome and life saved by intubation.

Dr. Hailes, of Albany, reported two cases in which intubation was practised successfully.

The discussion was continued by Dr. Brush, of Mount Vernon, who gave the operation the name of "intubation."

Dr. A. F. Currier, of New York, read a paper on

THE PALLIATIVE TREATMENT OF CANCER OF THE UTERUS IN ITS LATER STAGES.

He first referred to the origin of the term cancer, and then to the pathology of the disease. He then made some remarks on the question of local and constitutional origin, and also on the question of radical removal. The weight of opinion tends toward the view that it is of local origin, but that it reappears, and that radical cure after its first stages have been passed is impossible. The disease does not seem to be likely to be put on the list of affections due to a bacillus, and there are still too few data to enable one to speak with positiveness concerning the possibility of its originating by inoculation.

As to classification, he follows Waldeyer, and calls all the forms epitheliomata. By later stages he meant the period when constitutional infection has almost certainly occurred, the uterus is fixed, and ulceration exists to a greater or less degree.

If the patient can bear the operation, he advocated the removal of all the tissue which can be so removed with the scissors, then with the curette, and then, after the surface is thoroughly dried, apply the Paquelin cautery at red heat over the entire field of operation. After removal of the slough, the surgical treatment will consist of vaginal irrigations of hot water, and suitable topical applications. Medicinal curative treatment plays an unimportant part. The hygienic and dietetic treatment are very serviceable.

The paper was discussed by Drs. Jacobi, Lewis, and Janvrin, of New York; Goff, of Cazenovia, and a delegate from Brooklyn.

Dr. Samuel Sherwell, of Brooklyn, exhibited a set of ingeniously devised

NASAL, PHARYNGEAL, AND LARYNGEAL SCISSORS.

It is an absolutely pointless scissors, with joints, so that it has four blades.

Dr. A. Jacobi, of New York, read a paper

ON CREMATION,

sent by Sir Spencer Wells, of London, England, honorary member, in which purifying by fire was advocated.

Dr. S. Van Etten, of Port Jervis, Vice-President, in the Chair.

Dr. Martindale, of Richmond County, read an abstract of a paper, in which he related a case of

THROMBOSIS OF THE RIGHT RADIAL ARTERY COMPLICATING ENDOCARDITIS,

occurring in a patient considerably beyond the middle period of life.

Dr. W. Gill Wylie, of New York, read a paper entitled

PRACTICAL OBSERVATIONS IN ABDOMINAL SURGERY.

1. The use of hot water within the peritoneal cavity after laparotomy, for the purpose of preventing shock.
2. The use of laxatives and enemas after laparotomy and in septic peritonitis.
3. The abuse of tapping abdominal tumors.

He gave a synopsis of one hundred and twenty-five cases of laparotomy.

INVITED GUESTS.

Drs. W. H. Murray, G. L. Ullman, W. J. Nellis, and R. N. Steenberg, of Albany; C. B. Herrick, of Troy; F. L. Classen, F. D. Morrill, Henry Hun, and J. F. Barker, of Albany; C. W. Wilbur, of Rochester; D. W. Houston, of Cohoes; E. H. Howard, of Monroe County; J. S. Van Vechten and J. B. Ransom, of Franklin County.

The Society then adjourned, to meet in the Assembly Chamber at eight o'clock, to listen to the President's annual address.

Evening Session.

THE PRESIDENT'S ANNUAL ADDRESS.

The Society met in the Assembly Chamber, and listened to the entertaining and instructive address of the President, Dr. W. S. Ely, of Rochester. His theme was

THE PHYSICIAN IN SCIENCE AND LETTERS,

which was elaborated under the title, "The Achievements in Science and Letters of Men who have been connected with the Medical Profession."

The illustrations were taken from those whose names have been most intimately connected with philosophy, general literature, science (other than medical), and travel.

Philosophy.—Dr. John Locke, who has been called the greatest of English philosophers, was born in 1632. His first patient (while a student in medicine at Oxford, 1655) was Lord Ashley, afterward Lord Shaftesbury, on whom he diagnosticated empyema, performed an operation, and saved his life. Sydenham became acquainted with Locke, and formed a high idea of his medical skill. Locke, in turn, endorsed Sydenham's theory of the proper mode of treating disease.

Never of a strong constitution, Locke is obliged to leave England for the warmer climate of France. He returns to England and takes his degree of Bachelor of Medicine in 1674, in his forty-second year, but is again forced to travel for his health. He speaks of health as

"the only mistress he has for a long time courted, and so coy a one that he thinks it will take up the remainder of his days to obtain her good graces, and keep her in good humor."

In 1670 Locke sketched the first outline of his immortal essay concerning "Human Understanding," an essay which is said to have "done more than any other single work to rectify prejudice, to undermine established errors, to diffuse a just mode of thinking, to excite a fearless spirit of inquiry, and yet to contain it within the boundaries nature has set to the human faculties." He *sketched the outline*, but to complete the work twenty years were required.

But while Locke is the most distinguished medical representative in philosophy, there are others whose names deserve mention.

Few of us, perhaps, think often of Mr. David Hartley, whose name is connected with English philosophy. He was the son of a clergyman, born in 1705, and in his fifteenth year was sent to Jesus College, Cambridge. Like Locke, he was destined for the church. It is said that he led the life of a benevolent and studious physician. If he had given his time exclusively to medicine, he probably would have been forgotten. At the age of twenty-five he is absorbed in investigations into the cause of sensation. Sir Isaac Newton had raised the question whether vision might not be effected by the vibrations of a subtle medium which pervades all bodies, and Hartley amplified the idea into a system, affirming that vibrations small and large of the medullary substance of the nerves accounted for all of our sensations and ideas. He was the first to attempt to explain psychological phenomena on physiological principles.

The fame of Erasmus Darwin, the grandsire of the distinguished Charles Darwin, rests more on his contributions to philosophy and poetry than on his medical achievements. He is known as the author of a poem called "The Botanic Garden," and a philosophical treatise on disease, entitled "Zoonomia."

Schelling, the distinguished German philosopher, studied medicine, but immediately turned his attention to philosophy.

In France philosophy found a medical representative in Cabanis, who made valuable contributions to the physiological studies of mind.

It has been said that Cabanis "lays open our moral structure with his dissecting-knives and real metal probes, and exhibits it to the inspection of mankind by Leuwenhoeck microscopes and inflation with the anatomical blow-pipe." "Thought," he is inclined to hold, "is still secreted by the brain, but poetry and religion are the product of the small intestines, and must be cultivated medically by castor-oil."

In *Literature*, as in philosophy, medicine has had its part in shaping great minds, and one of the most charming of English writers is Dr. Oliver Goldsmith. The son of a clergyman and of the daughter of a clergyman, Goldsmith was designed for the church; but he was rejected by the bishop, before whom he appeared in red breeches for holy orders. Next he is urged to take up law, but this has no attractions for him; and finally physic is deemed the profession for which he is suited. So he goes in 1752 to Edinburgh, and spends two winters there in the study of medicine. He probably took the degree of doctor of medicine at Padua, but "all of his medical science gathered in foreign universities could not gain him the management of a pestle and mortar."

His friend Dr. Sleigh encouraged him to begin medical practice, and so he settles in Bankside, Southwark, where he endeavors to practise among the river-side poor. In the tarnished finery of a second-hand suit of green and gold, with a shirt and neckcloth of a fortnight's wear, he was, as he said to someone who asked him about his prospects, "practising physic and doing very well."

How much this reply is like the answer the young physician, starving and doing nothing, often gives to those friends to whom he is unwilling to admit his trials, hardships, and ill-success! But Goldsmith was struggling with poverty.

Among physicians, in literature, Sir Thomas Browne was mentioned, who pursued his medical studies at Oxford, Montpellier, and Padua, taking his degree of Doctor of Medicine at Leyden about 1634. He then returned to England and settled down as a physician. For recreation he wrote "Religio Medici," which during his life passed through eleven editions, being translated into Latin, Italian, German, Dutch, and French. More than thirty imitations of the book were published, which either copied the plan or stole the title. Lord Lytton called the "Religio Medici" one of the greatest prose poems in the language.

An interesting article could be written of the life of Doctor Tobias George Smollett, whose contributions to fiction and history have given him a permanent place in literature.

After studying medicine at Glasgow, he was made a physician in 1749, and commenced practice in London.

If time permitted, detailed reference might also be made to Sir James Mackintosh, who obtained his diploma in Medicine at Edinburgh in 1788, and achieved distinction as author, orator, and statesman; to Dr. John Brown, of Edinburgh, and to many others.

In *Poetry*, too, physicians, or those educated for physicians, have attained fame. All scholarly physicians claim Keats as one of their body. He was born of humble parentage, in London, 1795, and after receiving a fair education, was apprenticed at the age of fifteen to a surgeon. He died of consumption, at the age of twenty-four, and was buried in the English Cemetery at Rome, of which Shelley said that it was beautiful enough to make one in love with death. "Here lies one whose name was writ in water," was the epitaph Keats directed for his grave, so evanescent did he believe his reputation would be.

Another poet connected with the medical profession is George Crabbe. On leaving school, in his fourteenth year, he was apprenticed to a rough country doctor, and had to share the bed of the doctor's stable-boy. After six years of study, during which time he has written several poems, he proceeds to London, where he had a narrow escape from being carried before the Lord Mayor as a resurrectionist.

Mark Akenside, a physician as well as a poet, was the son of a butcher, who maimed him for life by a cut from his cleaver. When nineteen years old, he is sent to Edinburgh to study for the ministry. He soon revolts from divinity, and begins to study medicine. After three years spent in Edinburgh, he goes to London, where he obtains the degree of Doctor of Medicine in 1774. He was considered among the poets the best Greek scholar since Milton, and is described as a stiff-limbed, starched personage, with a lame foot, and pale, strumous face, a long sword, and a large, white wig.

Some may also recall Sir Richard Blackmore, who, although he obtained eminence and practice as a physician and wrote many treatises on the art of healing, is best remembered by his poetry, most of which he composed while visiting his patients. Pope said: "There's Sir Richard, in that rumbling old chariot of his, between Fleet Ditch and St. Giles pound, shall make you half a Job."

Lastly, reference may be made to Sir Samuel Garth, physician in ordinary to King George the First. He delivered the Harveian oration in 1697, and wrote a poem on "The Dispensary" at the time this charity was first instituted in London to counteract prescribing by the apothecaries over their counters.

But in *Science*, also, we have distinguished representatives in men who chose the medical profession, and were led by its study into some field of scientific research with which medicine is allied. No more interesting illustration of this can be cited than Doctor Louis

Agassiz. He was the son of a Swiss clergyman and early showed a fondness for natural science. At fifteen years of age a commercial life is projected for him, but so strongly does he beg to be permitted to continue his studies that he is sent to Lausanne to school. His uncle, who was a physician, is impressed with his fitness for a medical career, and advised that he should be permitted to study medicine. In 1826 Agassiz is found at Heidelberg, where are teachers whose influence upon him must have been great. His mother, who was the daughter of a physician, is fearful that he will give up his medical studies, so she writes to him: "How is it that you look forward only with distaste to the practice of medicine? Have you reflected seriously before setting aside this profession? Indeed, we cannot consent to such a step." His father shares the mother's feelings, and strives to repress the natural history bent in his son. Thus he writes: "If it be absolutely essential to your happiness that you should break the ice of the two poles in order to find the hairs of a mammoth, or that you should dry your shirt in the sun of the tropics, at least wait till your trunk is packed, and your passports are signed, before you talk with us about it." . . .

But the study of natural history he cannot abandon, and he finally writes to his father, "I hope yet to prove to you that with a brevet of a doctor as a guarantee, natural history may be a man's bread-winner, as well as the delight of his life."

He died in 1873, regretting that he could not live four more years, in order to complete the work he had contemplated. "His daring conceptions were only equalled by the unwearied industry and genuine enthusiasm with which he worked them out."

Any allusions to the achievements of physicians in other fields of science than medicine would be incomplete which omitted reference to Copernicus, "the Columbus of the heavens," "the setter forth of truths hitherto unknown, and the impugner of the rights of time-honored dogmatism." He obtained the degree of doctor at Padua in 1499.

Scanning the heavens by night, he exercised by day what Dean Milman calls "that blessed privilege of the Christian physician—the gratuitous care of the poor."

A century later Galileo, while prosecuting his medical studies at Pisa, invented the pendulum, and used a modification of it, known as the pulsilogon for accurately counting the pulse.

Travel.—The name of Elisha Kent Kane, M.D., will ever be prominently associated with Arctic exploration. He was graduated in medicine in Philadelphia in 1842. His restless spirit soon led him to enter the U. S. Navy as surgeon, and to make a voyage around the world. Next he served in the Mexican War. In 1850 he joined the First Grinnell Expedition in search of Sir John Franklin, and in 1853 made a second voyage for the same object.

Mungo Park may not be remembered by all as Dr. Mungo Park. He was designed by his father for the Church, but preferring the medical profession, was apprenticed, when fifteen years of age, for three years to one Thomas Anderson, a surgeon of Selkirk. At the expiration of his service as surgeon's apprentice he seeks Edinburgh, and spends three years there in studying medicine. Imbued with a desire to travel, he sails to Africa, under the auspices of the African Association, and returns in 1797 with the proud distinction of being the first of modern Europeans to reach the well-nigh fabulous waters of the Niger.

Lord Brougham said: "In Mungo Park the world has lost a great man, and one who was as well qualified, as he was inclined, to have been one of its greatest benefactors."

But great as Dr. Park was, he but prepared the way in African exploration for his still greater fellow-countryman, Dr. David Livingstone, whose career and history must be fresh in the minds of all. He was born in Scotland in 1813. In his tenth year we find him working in a cotton-mill, and after the hard work of the day striving to obtain some advantages from a night-school. His parental training had been markedly religious in its character, and Livingstone was early led to determine to devote himself to the alleviation of human misery.

His medical degree is obtained in 1840, his graduating thesis being upon the Stethoscope. "It was with unfeigned delight," he says, "that I became a member of a profession which is pre-eminently devoted to practical benevolence, and which, with unwearied energy, pursues, from age to age, its endeavors to lessen human woe."

In bringing to a close, a review of the lives of certain physicians whose reputation had been made in other callings than medicine, Dr. Ely desired to state that allusion to living exemplifications of the subject had been purposely omitted.

It would be observed that men had been led, in some cases by choice and in others by necessity, to unite other studies with that of medicine, or to subordinate the latter to the former. The "Religio Medici" was written, as the author affirms, for his personal amusement primarily. Dr. Hartley's philosophical work was his recreation. Every physician, who can command time, may find recreation in studies of a literary or scientific character, and great satisfaction in the results of such studies. It had, too, been made apparent, that the study of medicine had often suggested and aided the subsequent prosecution of other pursuits. To but few, indeed, is it given to frame an essay to rank with that of Locke, to create a "Vicar of Wakefield," to compose an "Ode on a Grecian Urn," to rival the original work of an Agassiz, or to lay bare the secrets of an unexplored continent. Among the number who have enriched philosophy, or adorned literature and poetry, or advanced science, or added to our knowledge of unknown regions of the globe, those who have been connected with the medical profession have a special claim upon our recognition and admiration.

The Society gave the President a vote of thanks for his instructive and interesting address, and then adjourned to participate in a banquet to be given at the Delavan.

THURSDAY, FEBRUARY 3D—THIRD DAY—MORNING SESSION.

The Society was called to order by THE PRESIDENT.

Prayer was offered by REV. H. A. STARK.

DR. CHARLES H. PORTER, of Albany, offered resolutions giving a vote of thanks to Sidney Ringer and Sir Spencer Wells for their exceedingly valuable contributions, and that their papers be referred to the Committee on Publication.

CONTAGIOUS OPHTHALMIA.

DR. LUCIEN HOWE, of Buffalo, offered the following resolutions, which were adopted:

Resolved, That a committee of three be appointed to investigate the question of blindness due to contagious ophthalmia in this State and the United States, and recommend means for its prevention.

Resolved, That the Society respectfully requests the President of the United States to accord such facilities for prosecuting the investigation as may be at his command.

Resolved, That this Society asks officials in charge of institutions to furnish any information on the subject which they may have.

REPRINTS OF THE PRIZE ESSAY.

DR. CARPENTER, of New York, moved that reprints of the prize essay on "Sanitation of School Life and Schoolhouses" be distributed to all municipal and other authorities and officials having under their management schoolhouses.

The motion was supported by Drs. Jewett, of Canandaigua; Mercer, of Syracuse; and S. B. Ward, of Albany, and the number was limited to fifteen hundred copies, in the discretion of the Secretary.

Dr. W. H. Richardson, of New York, was elected an invited guest.

Drs. C. S. Allen, Rensselaer County, and H. Bendell, Albany, were elected permanent members.

Dr. L. D. Bulkley, of New York, read a paper on

SYPHILIS OCCURRING IN CONNECTION WITH OTHER DISEASES OF THE SKIN.

Acne, eczema, psoriasis, and tænia versicolor were considered, also chancroid and gonorrhœa.

THE REPORT OF THE COMMITTEE ON NOMINATIONS

was read by W. E. Ford, of Utica, Secretary.

President—Alfred L. Loomis, of New York.

Vice-President—A. M. Phelps, of Chateaugay.

Secretary—William Manlius Smith, of Syracuse.

Treasurer—Charles H. Porter, of Albany.

Censors—Southern District: J. S. Warren, New York; M. B. Chase, Brooklyn; W. H. Helm. Eastern District: J. Lewi, Albany; Thompson Burton, Montgomery County; L. McLean, Troy. Middle District: J. G. Orton, Binghamton; Robert Frazier, Oneida County; I. N. Goff, Cazenovia. Western District: Theodore Dimon, Cayuga; M. S. Kettenger, Niagara County; David Littele, Rochester. Of the College of Medicine, Syracuse University: Harvey Jewett, Canandaigua.

Committee of Arrangements—S. B. Ward, of Albany; E. L. Partridge, of Brooklyn; F. C. Curtis, of Albany.

Committee on By-Laws—W. C. Wey, of Elmira; H. G. Piffard, of New York; William Manlius Smith, of Syracuse.

Committee on Hygiene—E. V. Stoddard, of Rochester; F. C. Curtis, of Albany; A. N. Bell, of Brooklyn; J. P. Creveling, of Cayuga; E. Hutchinson, of Utica; W. H. Bailey, of Albany; E. F. Brush, of Mount Vernon.

Committee on Legislation—Laurence Johnson, of New York; F. R. S. Drake, of New York; H. Bendell, of Albany.

Committee on Ethics—A. Jacobi, of New York; A. Matthewson, of Brooklyn; J. W. Whitbeck, of Rochester.

Committee on Prize Essay—George F. Shrady, F. P. Foster, Wesley M. Carpenter, of New York.

Committee on Publication—Wm. Manlius Smith and Alfred Mercer, of Syracuse; Charles H. Porter, of Albany; and Wesley M. Carpenter, of New York.

Honorary Members—E. Landolt, of Paris; James Grant (Bey), of Cairo; K. A. P. Grinnell, of Burlington, Vt.; Bennet Dowler, of New Orleans.

Eligible to Honorary Membership—H. C. Allchin, of London; D. N. Wilcox, of Lee, Mass.

Delegates to Massachusetts State Medical Society—Daniel Lewis, of New York; C. H. G. Spencer, of Watertown.

Delegate to New Jersey State Medical Society—A. P. Morrow, of New York.

Delegate to Pennsylvania State Medical Society—F. A. Henkel, of Erie County.

Delegates to New Hampshire State Medical Society—O. B. Douglas, of New York; Harvey Jewett, of Canandaigua.

Delegates to Vermont State Medical Society—M. H. Burton, of Troy; W. O. Moore, of New York; A. M. Phelps, of Chateaugay.

Delegate to Connecticut State Medical Society—N. C. Husted.

Delegate to Canadian Medical Association—Lucien Howe, Buffalo.

PAPERS READ BY TITLE.

By J. V. Kendall, Baldwinsville, "The Obstetrical Experience of a Country Practitioner;" by Laurence Johnson, New York, "The Therapeutic Use of Bismuth;" by A. Jacobi, New York, "Treatment of Membranous Croup," "Peritonitis of the Infant;" by F. W. Henkel, Buffalo, "Irregularities of Septum Narium;" by George Henry Fox, New York, "Errors in the Treatment of Skin Disease;" by A. Dann, Rochester, "An Unusual Method of ridding the Male Bladder of Small Calculi;" by Franklin Townsend, Jr., Albany, "Ovulation and Menstruation;" by J. R. Leaming, New York, "Diagnostic Areas of the Human Chest;" by H. Knapp, of New York, "Ninth and Tenth Series of One Hundred Consecutive Cataract Extractions;" by Wm. Hailes, Albany, "Obituary Sketch of Henry March, of Albany;" by H. D. Didama, Syracuse, "Obituary Sketch of R. W. Pease, of Syracuse;" by A. Hutchins, Brooklyn, "Cascara Sagrada."

AMENDMENT TO THE BY-LAWS.

An amendment to the By-laws was adopted which gives the President the power, *ad interim*, to receive and accept resignations from committees, and to fill the vacancies that may thus occur.

Dr. Pillsbury, of Middleton, read a paper on "Albuminuria treated by Glonoin, and Bromide of Potash in the Treatment of Rheumatism."

VOTES OF THANKS.

On motion by Dr. Laurence Johnson, New York, the thanks of the Society were voted to all railroads which had given reduced rates; also to the custodians of the City Hall.

On motion by Dr. Vander Veer, Albany, the Society gave the retiring President a vote of thanks for the able and impartial manner in which he had presided over its deliberations.

Drs. W. O. Marcelius and Albert Marsh were elected invited guests.

Dr. Glover, of Amsterdam, exhibited a modification of Chadwick's gynecological table.

The committee on Dr. Howe's resolution concerning contagious ophthalmia consists of Drs. Lucien Howe, of Buffalo; C. R. Agnew, of New York; and E. V. Stoddard, of Rochester.

Several more papers were read by title and the Society adjourned.

Simple Apparatus for Staining Tubercle Bacilli.—Rapidly to prepare an aniline-water-fuchsin solution Dr. Saccharow uses the following practical apparatus: To a common holder with stand, as used in laboratories to keep reaction tubes, etc., in an upright position are attached: 1. A glass bottle with the bottom upside down and filled with aniline water. Whatever too much aniline is present accumulates in the lower part. Through the neck pass two glass tubes. One is intended to admit air, the other is provided with a piece of rubber hose and some little arrangement, as a clamp, for stopping the flow of the aniline water. 2. A funnel and paper-filter, which fits into a glass tube just beneath the bottle, and which contains fuchsin-crystals, and has a pointed end. 3. Underneath this is another funnel and filter, through which the aniline water, now containing fuchsin, gradually passes from above into a watch-glass, so that the solution is filtered the second time. With this simple apparatus one may prepare at any time a fresh solution of fuchsin in aniline water. As soon as the fluid is obtained the clamp on the rubber hose is closed, and the apparatus ceases working until the clamp is opened and the aniline water allowed to flow out over the fuchsin again.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, January 10, 1887.

STEPHEN SMITH, M.D., CHAIRMAN; A. B JUDSON, M.D., SECRETARY.

OFFICERS FOR THE ENSUING YEAR.

DR. R. F. WEIR was elected chairman, and Dr Robert Abbe secretary.

SUPPURATIVE NECROSIS OF THE JAW—ABSCESS OF THE FRONTAL SINUS.

DR. GOODWILLIE related the history of a patient who had been sent to him by the late Dr. Farnham in, 1880. There was great swelling of the face and neck from necrosis of the jaw, and suppuration following disease of one of the lower molars. Treatment was by aspiration with the hypodermic needle. Upward of twenty operations were thus performed under the nitrous oxide anæsthetic, with remarkably favorable results, as shown by wax casts taken before and after treatment.

Another patient was shown, who had received a blow from a hot cinder from the Elevated Railroad. The result was an abscess involving the sinuses of the frontal bone. Dr. Goodwillie had trephined and inserted a platinum drainage-tube in the inner and anterior part of the roof of the orbit. The manipulation of the platinum tube, and the treatment of the sinus by peroxide of hydrogen injections, was exhibited to the Section. The result sought in this case, and obtained in the preceding case, was recovery without disfigurement or deformity.

DR. GIBNEY discussed the subject of aborting abscesses of the face or elsewhere. He favored the bringing about of this result, and had seen many cases in which recovery from joint-disease had been attended with the disappearance of abscesses without direct treatment, and without discharge.

DR. R. W. TAYLOR read a paper entitled

IODOFORM ERUPTIONS.

He first considered briefly the general toxic effects of the drug, and spoke of the necessity of their knowledge by those who used it, since it was generally so ill understood—particularly the mild form of the poisoning, the chief symptoms of which were increasing weakness, emaciation, and delirium, with all of their concomitant symptoms, all of which were frequently passed unrecognized as to their origin in the systemic action of iodoform. He then detailed a series of personal cases as well as those reported by Zersil, Fabre, Neisser, Treves, Goodell, Fifield, and others. The conclusions drawn from these cases were: First, that iodoform quite frequently produced in those who used it freely—assistants at hospitals and dispensaries—a mild erythema, particularly of the fingers and about cuts, which caused little or no uneasiness and ceased when the use of the drug was discontinued; secondly, in certain cases of open granulating wounds, a longer or shorter time after beginning the use of the agent, two forms of erythema might be observed, the one simple, superficial, and more or less extreme, the other well marked, attended with much œdema; both of these varieties might be complicated with papulation, vesiculation, pustulation, and in very bad cases with phlegmonous inflammation; thirdly, an eruption occurred from applying the agent to the throat or by smelling it, in which absorption of the drug occurred, and very soon severe dermal lesions of the face, head, hands, feet, etc., were seen; fourth, that in these cases there seemed to be a distinct iodoform idiosyncrasy, such as we see in some cases of quinine, iodide of potassium, and ipecac. Dr. Taylor considered further, minutely, the divisions of eruptions, and entered briefly into their pathogenesis.

DR. JACOBI said that Dr. Taylor's cases reminded him of the frequent results of the administration of small doses of iodide of potassium. He recalled one case in particular, in which a young man had suffered severely from stomatitis, conjunctivitis, and urticaria.

DR. GIBNEY stated that he frequently resorted to the application of iodoform, for the excoriations caused by adhesive plaster in the treatment of cases of hip-disease, but he had as yet failed to observe any unpleasant effects beyond the occurrence of slight itching in one or two instances.

DR. P. A. MORROW had occasionally seen erythematous and œdematous infiltrations from the topical application of iodoform, but had never observed a generalized eruption from this cause. Some cases produced papules and vesicles, and in a few cases there had been urticaria, and even erysipelas. The eruption appears after protracted use of the drug, and its acme may not be reached till after the application has been discontinued. These effects of the use of iodoform are the result of the contained iodine. They are analogous to the groups of symptoms known as iodism. A textural predisposition of the skin permits the drug to produce irritation of the sensory nerves, causing reflex paralysis of the vaso-motors of the vascular area affected. The result is dilatation of the vessels, with erythema and various degrees of dermatitis. Dr. Morrow knew of no eruptive accidents from the internal use of iodoform.

DR. C. S. WOOD had seen several cases in children, and considered that the drug excites a neurosis in susceptible persons, like the neurotic effect which is produced in some persons by the administration of five grains of blue pill, or the smell of ipecac.

DR. STEPHEN SMITH recalled the case of a physician who, after receiving the iodoform spray every day for two or three weeks for a follicular tonsillitis, was suddenly attacked with drowsiness and mental hebetude, so marked and persistent that he spent a large part of the day in studying his visiting list, making frequent but vain attempts to formulate his thoughts in words. There was headache but no fever, and recovery was rapid and complete.

The Section then adjourned.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

Stated Meeting, January 27, 1887.

ALEXANDER S. HUNTER, M.D., CHAIRMAN; HENRY GRISWOLD, M.D., SECRETARY.

OFFICERS FOR THE ENSUING YEAR.

DR. E. L. PARTRIDGE was elected Chairman, and DR. L. EMMETT HOLT Secretary.

DR. S. HENRY DESSAU read a paper entitled

CERTAIN PECULIAR FEATURES OF BRONCHITIS AS IT OCCURS IN CHILDREN.

Before speaking of the subject proper, Dr. Dessau referred to the method of examining the thorax in children, and said that the chest should always be completely uncovered and that auscultation should be done with the stethoscope. The temperature of the child should always be taken, and he preferred to do it in the rectum.

Bronchitis limited to one lung.—Of these cases Dr. Dessau had seen several; in three the smaller bronchi were involved, as determined by the character of the râles and the absence of bronchial respiration. In some there was elevation of temperature to 102° to 104° F., and the pulse and respiration were accelerated. It was the common opinion that bronchitis attacks both lungs, and such was the case ordinarily; but it was equally true that it might affect only one lung, or only a portion of one lung, or it might be confined to the bronchi of the

first, second, or third order. The interesting point in these cases was the differential diagnosis between the bronchitis and pneumonia and pleurisy.

The next point of special interest was the fact that a slight bronchitis may give rise to enlargement of the lymphatic glands at the roots of the lungs, to be followed rapidly by caseous degeneration, meningitis, and general tuberculosis.

Bronchitis more or less severe may occur in the course of summer diarrhœa in children. He regarded the cause as analogous to that which produces pulmonary congestion in cholera.

Treatment.—Under this head attention was first directed to hygienic conditions and prophylactic measures. As a prophylactic cold bathing was especially recommended. Except in severe cases it was not necessary to keep the child in the house, provided it was kept warm while in the open air. In private practice the child may be kept in a room well ventilated and having a temperature of about 65° F. The addition of steam in the air of the room would be of advantage in severe cases, and it might contain a small quantity of the vapor of turpentine. He seldom uses opium, but relies upon stimulating embrocations, mustard poultices, aconite, belladonna, ipecac, spirit of mindererus, cod-liver oil with or without the hypophosphites of lime and soda, muriate of ammonia, and the children should have abundance of water to drink, as had been recommended by Dr. Jacobi.

Dr. L. Emmett Holt agreed with Dr. Dessau concerning the use of the stethoscope, and also the uselessness of attempting to auscultate the chest through the clothing.

As to unilateral bronchitis he thought that a temperature of 103° or 104° F., persisting for a week or ten days, would indicate broncho-pneumonia rather than bronchitis. Persistent high temperature was perhaps the most reliable symptom in favor of broncho-pneumonia in making a differential diagnosis.

Concerning bronchitis attended by enlargement of the bronchial glands, followed rapidly by meningitis and general tuberculosis, it had seemed to him that these cases were better explained on the supposition that meningitis and pulmonary tuberculosis began at the same time.

With regard to medicinal agents, he had used terebene with very satisfactory results, particularly in the chronic cases when a hard, dry cough persisted—even though the physical signs had cleared up—and the child was far from being well.

Dr. J. H. Fruitnight agreed in the main with what Dr. Dessau had said in his paper, yet there were some points in which he should differ with him. He thought that more stress should have been laid on inspection of the chest, and also that the pleximeter and hammer were preferable to the fingers in making percussion. Although the stethoscope should be our main reliance, auscultation by the unaided ear should not be discarded entirely. He thought, also, that the cases in which there was enlargement of the lymphatic glands and secondary development of general tuberculosis were very apt to be overlooked. There was one symptom which should have received more prominence, and that was a peculiar spasmodic cough the clang of which resembled whooping-cough, but the physical signs and the preceding history of the case would enable us to readily eliminate that affection.

With regard to persistent high temperature, he should regard it as most probable that it was evidence of broncho-pneumonia rather than bronchitis.

As to treatment, he would be chary concerning the use of antimonials. What Dr. Holt had said with regard to terebene he could corroborate. He had found the tincture of sanguinaria to be a very serviceable remedy. He used the preparations of opium merely for the purpose of securing rest and allaying an irritative cough.

Dr. E. L. Partridge said that there was one point especially in the paper which was of practical importance, and that was with reference to allowing the children to go about while suffering from bronchitis, particularly out of doors under proper precautions as to clothing, etc. It had always seemed to him that there was more danger in carrying these children from one room to another than in taking them out. For the difference in temperature of rooms was much greater than was generally supposed. To test or to regulate the temperature of any room he always insisted that the thermometer should be placed on a level with the probable situation of the child while occupying it.

He had found the camphorated tincture of opium, given in small doses frequently repeated, a very efficient remedy; it diminishes the secretion of mucus, steadies the heart, and overcomes restlessness and pain.

Dr. T. J. Kearney said it was not till three or four years ago that he had his attention directed to the frequency of the occurrence of unilateral bronchitis, and since that time he had seen several cases. Poultices, intelligently applied, he regarded as very serviceable.

The Chairman was quite in accord with what the author of the paper had said, and would criticise only so far as to say that he believed it to be better in preparing a mustard poultice, to use a difinite quantity of mustard to a certain quantity of flaxseed meal, as 1 to 16, rather than to dust the mustard upon the surface.

Dr. Dessau, in closing the discussion, said, with regard to persistent high temperature being a symptom of broncho-pneumonia, that he was inclined to take that view of the case, but from the fact that there was no bronchial respiration nor dulness, he was led to believe that it was one of unilateral bronchitis involving the smaller bronchi. So far as antimonials were concerned, he had advised them in such small quantities that there would probably be no danger in so using them.

The Section then adjourned.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, January 4, 1887.

C. L. Dana, M.D., President, in the Chair.

Dr. W. H. Porter presented

THE KNEE-JOINT AND SPINAL CORD IN A CASE OF SPINAL ARTHROPATHY.

The patient had suffered from locomotor ataxia in a typical form for about six years. The joint troubles developed several years before death. The knee was enlarged, there was partial dislocation and venous hypertrophy with rarefication. In the joint were found a large number of loose cartilages, the articular cartilages were worn away, and there was eburnation of bone.

In the discussion by Dr. L. Weber, Dr. Sachs, Dr. Starr, the President and others, the recent views of Virchow, that the spinal arthropathy was not a special trophic disorder characteristic of tabes, was referred to. The general opinion seemed to be that the arthropathy was a condition resembling that of rheumatoid arthritis, but somewhat modified by the peculiar condition of the nerves and nerve-centres in posterior sclerosis.

Dr. Porter also presented the spinal cord in a case of

LOCOMOTOR ATAXIA RUNNING ONLY A SIX WEEKS' COURSE.

The patient had been in the Presbyterian Hospital, and his history was obtained with special care. No evidence whatever of any spinal symptoms previous to about six weeks before death was obtained. There was no history of diphtheria or an infective disease.

Sections of the cord had been made by Dr. C. L. Dana, stained by Weigert's method and with aniline blue.

They showed a very marked degree of posterior sclerosis affecting both the columns of Goll and of Burdach.

NOTE ON APHASIA WITH REFERENCE TO LOSS OF NOUNS.

Dr. Putnam-Jacobi read a paper on that form of aphasia in which the defect is limited to the loss of nouns. Seventeen cases out of a total of one hundred and sixteen analyzed offered this peculiarity, which had not failed to attract the notice of authors. Several explanations had been offered, none of which seemed to the writer completely satisfactory. Anatomical data were not at present sufficient to throw much light on the matter, further than to demonstrate that the symptom was probably always associated with diffuse, and not with focal, lesions. These lesions could not fail to lie on the sensory side of the speech mechanism, and for reasons detailed at length in the paper must especially involve the paths between the auditory and visual centres, through which the auditory impression or sign of the object became habitually associated with the visual impressions. The writer maintained that the act of speech always involved an entire proposition, framed in the supra-sensory concept centres, probably the superadded convolutions of Broadbent. This proposition constituted a verbal conglomerate, a unity to the mind expressing it, whatever the number of separate parts into which it might be broken up. Such actual verbal conglomerates remained in many primitive languages, as that of the Greenlanders and North American Indians, where entire sentences were often inflected like a single noun or verb. In our languages the conglomerate or proposition to be expressed is composed of the reminiscences of auditory signs which have become fused with similar reminiscences of visual impressions of things and their relations. If the visuo-auditory paths are interrupted the signs or names of things will be dislocated from their habitual association with the other characters of such things; while the visual impressions themselves remain and enter directly into the verbal conglomerate. All other parts of speech than nouns, expressing complete intellectual relations, and although remotely connected with impressions registered in the visual centre, are immediately associated only with the processes and registrations of the supra-sensory or intellectual centres. While these are intact, therefore, and unless focal lesions have altogether obliterated the memory of language, the speech of relations will be remembered and revived in expression. The objects which are involved in the relations of the conglomerate proposition will no longer be revived in consciousness by their names, but by means of their visual impressions only. These can be expressed by gestures, mimicry, or periphrases, the loss of the auditory sign being thus compensated.

PERIPHERAL NEURITIS AND THE PAINFUL PARALYSES OF EARLY LIFE.

Dr. H. D. Chapin read the paper (see Medical Record, p. 57).

In the discussion, Dr. M. Allen Starr did not know of any recorded case in a patient under twenty-four years of age in which a lesion of a peripheral nerve had been found at autopsy which would account for the paralysis, and while there was great probability in the statements made by the author, they yet lacked confirmation by autopsy. The points had been brought out very well with regard to the distinctions between peripheral neuritis and anterior polio-myelitis, but he would take exception to what had been said regarding the rapidity of the onset. There were many cases of acute onset of peripheral neuritis, the patient having fever and chill, and the limbs within twenty-four hours becoming entirely immovable. Too much attention could not be given to the usually great tenderness in the muscles and nerves in multiple neuritis.

Dr. Rudisch said that he was the first to observe, as long ago as eight or nine years, a form of polio-neuritis leading to paralysis and atrophy, and which followed affections of the joint, often so-called rheumatic affections. We now saw often enough an affection of one or more joints with inflammation, followed after a while by paralysis usually curable.

Dr. Fisher said a girl thirteen or fourteen years of age was brought to the dispensary with the history that one morning after taking cold she woke up with paralysis of the upper and lower extremities. At that time she had only paralysis in one leg, which he supposed, without thought of neuritis, to be ordinary polio-myelitis. Rapid improvement took place, and she recovered within six weeks, and the minister who brought her reported the case as one cured by faith. Dr. Fisher was unable to say whether the case was an affection of the anterior cornua or one of multiple neuritis.

Dr. Sachs thought we should not be influenced too much by the present fashion, and call all or most of the cases formerly regarded as polio-myelitis cases of multiple neuritis. Referring to one of the cases related in the paper, and the symptom of pain, he said too much stress should not be laid upon it unless it was severe, persistent, and located distinctly along the tract of a peripheral nerve.

Dr. Leszynsky said that the pains present in some of Dr. Chapin's cases reminded him of the pain from straining of the tendons of the extensor muscles which had been for some time in a paralyzed state.

Dr. Chapin thought that a neuritis would occasionally explain cases which could not be accounted for on the supposition of a spinal lesion, and he would rather say halt to the universal spinal cause of disease. With regard to pain, it was difficult to locate it along a particular nerve in children, but in his cases it was acute and persistent, and not due simply to stretching of tendons.

Correspondence.

THE COMPENSATION OF EXPERT WITNESSES.

To the Editor of The Medical Record.

Sir: Your editorial in the Medical Record of January 8, 1887, concerning expert testimony and its compensation, suggests to me that the following references which I have gathered may be of interest to many in the profession.

During the past year, as a member of the committee on medico-legal matters appointed by the New Mexico Medical Society, I made a diligent search for information on this topic. Here are the results:

The decision of the Supreme Court of Alabama is the only one I learned of that was wholly adverse to the expert. *Ex parte* Dement, 53 Alabama, 389, is the title. The learned judges held that "in so testifying he would not be practising the healing art . . . he would be deposing only to things which he had learned in the course of his occupation or profession," etc. In Summers *vs.* State, 5 Texas (App.), 374, in 1879, the court followed the Alabama precedent closely.

The most important decision in favor of the physician was rendered in the Supreme Court of Indiana in 1877, and is entitled Buchanan *vs.* State, 59 Ind., 1. This is by far the most interesting and complete discussion of the whole subject, and should be well known to every physician. It was held that, "while a physician or surgeon could be required to attend as a witness to facts without other compensation than that provided by law for other witnesses, yet he could not be required to testify as to his professional opinion without the compensation of a professional fee. The professional knowledge of an attorney or physician is to be regarded in the light of property, and his professional services are no more at the mercy of the public, as to remuneration, than are the goods of the merchant, or the crops of the farmer, or the wares of the

mechanic." "When a physician testifies as an expert by giving his opinion, he is performing a strictly professional service," the exact reverse of the Alabama decision.

Curiously enough, this acute decision of the Indiana Supreme Court did not satisfy the bucolic legislators of that State, for in their Revised Statutes, 1881, Sec. 504, is a provision that "a witness who is an expert in any art, science, trade, profession, or mystery, may be compelled to appear and testify to an opinion as such expert" without other pay than that of an ordinary witness.

In U. S. *vs.* Howe (12 Cent. L. J., 193), the United States District Court for the District of Arkansas decided in the same manner as the Indiana Supreme Court.

There are statutes in Iowa, Rhode Island, North Carolina, and South Carolina, granting extra compensation to expert witnesses; that of Iowa seems to be the best—the "compensation to be fixed by the court with reference to the value of the time employed, and the degree of learning or skill required." South Carolina fixes the pay at $10 per diem in addition to the ordinary witness fees and mileage.

The New Mexico Medical Society has prepared a bill which is now before the Legislature at Santa Fé, which provides that any person, of whatever trade or profession, called to testify as to his professional opinions, shall receive extra compensation to be fixed by the court, the minimum to be $10 *per diem*, the amount to be regulated by the time and skill engaged, and providing that not more than two experts can be called on a side. The object of the last provision is to prevent the accumulation of excessive costs. Its passage intact is very doubtful.

In the Indiana decision are several references to cases of interest.

Webb *vs.* Paige (1 Carrington and Kirwein, 23), an English case in 1843. The expert was a cabinet-maker, and having objected to testifying without compensation, the Court (Maule, J.) held that a witness called to depose to a "matter of opinion depending on his skill in a particular trade has, before he is examined, a right to demand from the party calling him a compensation for his loss of time, and there is a distinction between a witness thus called and a witness who is called to depose to facts which he saw."

Greenleaf on Evidence: "The latter (an expert) is under no such obligation, and the party who selects him must pay him for his time before he will be compelled to testify."

Webb *vs.* Baird, 6 Indiana, 13. In favor of the expert, in this instance an attorney.

Blythe *vs.* The State, 4 Indiana, 525. Blythe, an attorney, objected to defending a pauper by order of the court, unless compensated. The Supreme Court sustained him.

People *vs.* Montgomery, 13 Abb. Pr. (U. S.), 207 (1871). Here it was held that an expert cannot be compelled to examine a case or otherwise prepare himself for testifying.

In the Texas case above it was decided that a physician may be compelled to testify as to the result of a post-mortem examination made by him, but he cannot be compelled to make such an examination.

Also Moch *vs.* City of Buffalo, 13 Rep., 251. Haynes *vs.* Mosher, 15 How. Pr., 216.

In Re Roelker, U. S. Dist. Court, Mass., 1854, the court decided in favor of the expert, in that case an interpreter.

Editorial in *Boston Med. and Surg. Journal*, December 22, 1881, concerning case in Superior Court, Boston, Mass. Court held "that a physician is not bound to give his professional opinion for nothing in court any more than anywhere else."

Other references are: "Duties and Privileges of Expert Witnesses," *Phil. Med. Times*, January 6, 1877; Reese's "Manual of Toxicology," Philadelphia, 1874; *Phil. Med. Times*, February 11, 1882, p. 332; *Phil. Med. News*, March 11, 1882, p. 283. See also Judge C. C. Fuller's decision in Michigan, case of State *vs.* Vanimmans, where the expert was sustained, in N. Y. MEDICAL RECORD, April 3, 1886, p. 395; *American Journal of the Medical Sciences*, October, 1882, p. 546.

The standard works of Ordronaux, Med. Jur., Sec. 114, Taylor, and Wharton have passages sustaining experts in their right to extra compensation; also Redfield is named. Honeyman's Practice and Precedents, Sec. 447. Snyder *vs.* Iowa City, 40 Iowa, 616. Code of Iowa, 1873, Sec. 3814. Dille *vs.* State, 59 Indiana, 15.

From Massachusetts I learn that "the common law permits the court to allow extra fees to experts, and such a fee is always allowed witnesses for the commonwealth. Medical experts usually receive $25 a day, and those from a distance sometimes get more; but this is optional with the court, and a physician can be compelled to testify for the usual witness fee." See this discussed by F. W. Draper, M.D., in *Boston Med. and Surg. Journal*, August 2, 1883, p. 98, where the other relations of the expert witness, besides his compensation, are well considered.

In the same journal, July 7, 1881, Dr. Walter Channing treats the same topic, and quotes a proposed law regulating expert testimony.

Again, in THE MEDICAL RECORD, June 25, 1881, p. 722, is mentioned certain action of the Rhode Island State Medical Association.

The most complete presentation of the subject is to be found in Lawson's "Expert and Opinion Evidence," where the Indiana decision is given in full, as well as that of the Alabama Supreme Court.

I have no doubt that a more thorough search than I have been able to make, so "far from the madding crowd," would reveal much more material on this subject, in which every physician has an equal interest. To favor completeness, let me add the references to Tidy's "Legal Medicine," and Mr. Henry A. Riley's contribution on the "Law of Expert Evidence" in the "Reference Handbook of the Medical Sciences." It is rather surprising that the opinion of an author so highly esteemed among all English-speaking people as Simon Greenleaf should not have constrained all our courts long ago to a unanimity of principle and action as regards compelling and compensating expert witnesses.

The other relations of the expert, whether as a partisan or an impartial scientific witness, his privileges and his woes in the courts, his duties and details as to his manner of giving his professional opinions, have all been much discussed also by physicians and by lawyers of liberal views.

FRANCIS H. ATKINS.

LAS VEGAS, N. M.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: While the case of Dr. Darby is fresh in mind, it seems proper to state that, during the November term of the District Court in this place, six physicians were kept for two days in attendance upon the court. The judge was called upon to order extra fees to be paid to witnesses who should be required to give expert testimony. He answered that he would be glad to order such fees if he had the power; but that when the Territorial Judiciary had been recently convened, for the purpose of holding a supreme court session, the matter was fully discussed, and the opinion expressed by every member that a district judge has no power nor authority in Dakota to order extra fees to be paid in cases where expert testimony is taken.

The shortest remedy, it seems to the writer, for such a state of things, is by legislation. The situation demands that a united effort be made to compass such remedy, and that you, by means of the powerful influence of your journal, effectually urge upon the various societies and members of the medical profession the importance of making an organized and simultaneous effort to secure

legislation in all the States and Territories, authorizing judges to order expert-witness fees in cases where expert testimony is taken.

When it becomes a matter of statute, the injustice and outrage to which medical expert witnesses are now so often subjected will end.

Respectfully,

S. A. Brown, M.D.

Sioux Falls, Dak., January 14, 1887.

SYPHILIS FROM VACCINATION.

To the Editor of the Medical Record.

Sir: The important case communicated by Dr. J. S. Prettyman to the Medical Record prompts me to ask space to refer to some other features of this vitally important subject. Several of my personal acquaintances having become affected with cancer, in some instances terminating fatally, I have been led to inquire into the probable cause of the serious increase of late in this terrible disease. The mortality in England and Wales from 1851 to 1860 was 421 per million; from 1861 to 1870 was 534 per million; from 1871 to 1880 was 553 per million. It is allowed by physicians that cancer may be due to impregnating the blood with impure matter, and it is obvious that there is no method by which this is done on so large a scale as in vaccination and revaccination. It is not denied that vaccination is an exciting cause of infantile syphilis, and according to the Registrar-General's returns—No. 433, dated 1877; and Infant Mortality, No. 392, dated 1880—the increase in this disease since vaccination has been made compulsory is fourfold. Mr. Hibbert, formerly Secretary to the Local Government Board, said, in July, 1880, that this terrible increase was one of the most unsatisfactory features of the Vaccination Acts, and a reason why further legislation was needed. Dr. William Forbes Laurie, late Medical Director of St. Saviour's Cancer Hospital, Regent's Park, was thoroughly convinced that the great increase of cancer was due to vaccination, and he wrote to several members of Parliament inviting them to visit the hospital, and witness the dismal results of the operation. He says this increase of cancer is "attributed by some medical men to the large amount of syphilitic disease, with which vaccine lymph is impregnated," and by others to the direct impregnation of healthy persons with lymph imbued with scrofulous and cancerous matter. The *British Medical Journal* for May 19, 1883, in a leading article on the increasing fatality of cancer, puts the mortality from 1850 to 1855 at 302 per million; while in the year 1875 it had risen to 480 per million; and, in considering the causes of this increase, says: "Our negligence in dealing effectually with other diseases may also favor its dissemination; for if syphilitic inflammation may become cancerous, it is clear that the spread of syphilis has scattered throughout the population innumerable possible seeds of cancerous degeneration." The *London Hospital Gazette*, a short time ago, said that fifty infants were admitted into one hospital within a month suffering from syphilitic disease, from some of whom vaccine lymph had been taken. This is an indication how the cancer-spreading virus may be distributed. It would be unbecoming in me to dogmatize upon a subject which is admitted to be a puzzle to the medical profession, but I venture to hope that some of the medical correspondents of your impartial columns who have had the opportunity which clinical experience affords will, in the interests of the public health, be able to say whether the suggestion I have made is borne out by facts.

Yours faithfully,

William Tebb.

National Liberal Club, Charing Cross,
London, January 11, 1887.

Vaccination is just now a profitable pastime for the old and young practitioner.

New Instruments.

A COMBINED CURETTE AND DOUBLE CATHETER.

By George E. Abbott, M.D.,

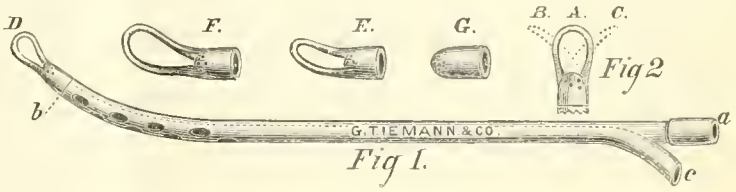
New York.

I send herewith a drawing of a double catheter with a curette attachment, which has been found to work well by my friends and myself in several cases.

It consists of a fac-simile of a double catheter lent to me by Dr. Edwin F. Ward, of this city, which has unusually large fenestræ for the free return of the injected fluid, to which may be attached the curettes *D*, *E*, *F*, on the round end of the catheter *G*.

The curettes are of various sizes, and dull or sharp, as desired.

For curetting the anterior surface of the uterus or other cavity, screw the curette on as far as it will go, when it will be in position, as at *D*, Fig. 1, or *A*, Fig. 2.



Figs. 1 and 2.

For the posterior surface, give the curette a half turn, when its concavity will look backward, and will attack the posterior surface well.

For curetting the sides, unscrew the curette a quarter turn or a three-quarter turn, when it will have the position of Fig. 2, *C* or *B*.

It will at first seem that, when placed in these positions, the curette would not attack its work, but would turn this way and that. That this is not the case can be demonstrated by curetting the sides of the hand as it grasps the instrument.

The curettes are attached by a fine thread and a long shoulder or tenon, as at *b*, and thus allow of the positions above indicated without loss of firmness.

In use, a Davidson's syringe or irrigating tube is attached to the catheter at Fig. 1, *a*, through which the antiseptic fluid passes, emerging at the little holes at the base of the curette *D*.

The return-current passes through the large fenestræ below *b*, and out at *c*, into a white receiving-vessel. (It will add much to the comfort of the surgeon to have a tube attached to *c*, thus avoiding wetting his hands, etc.)

The advantages gained are:

1. In making the parts thoroughly aseptic. The antiseptic fluid being allowed to run before entering the cervical canal, and during the time of operating.

2. The denuded surfaces are immediately covered by the antiseptic fluid before infection can possibly take place.

3. The detritus is immediately and fully removed.

4. The surgeon can see by the returns in his white receiving-bowl what he is doing—fungosities, membrane, pure blood, or clear antiseptic fluid.

5. No bacteria are introduced, as in the use of the ordinary curette.

6. No fungosities or detritus remain to decompose.

It is hoped that the instrument will be of service to the profession, who can obtain it from Messrs. Tiemann & Co., of this city.

Aural Troubles.—A French medical writer, in treating of the ear, says that this organ is subject to a number of painful affections, among which may be mentioned otitis, Wagner's music, etc.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 23 to January 29, 1887.

MORRIS, EDWARD R., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect about March 10, 1887, with permission to apply for an extension of twenty days. S. O. 6, Division of the Pacific, January 19, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 29, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	5
Scarlet fever	47	13
Cerebro-spinal meningitis	5	4
Measles	453	54
Diphtheria	109	33
Small-pox	23	3
Yellow fever	0	0

THE TREATMENT OF THREAD-WORMS IN CHILDREN.—Dr. Sidney Martin writes as follows to the *Practitioner* of October, 1886: "The complete cure of thread-worms in children is often very difficult. While the ordinary methods used, such as rectal injections of salt and water, infusions of quassia, and other remedies, do good for a time, yet they often fail to relieve the attendant symptoms of 'worms,' symptoms usually very irregular, and in some cases severe in character. In many cases, though the irritation about the anus is relieved by injections, the irregularity of the bowels and the disturbance of sleep remain the same. This is probably due to the fact that the habitat of the worms is higher up in the large intestines, where no remedy introduced by the rectum can reach them. In many cases I have found that rhubarb, in small doses, brings away large numbers of worms, and at the same time regulates the bowels, so that the use of injections may in most cases be dispensed with. The formula which I have found most useful is as follows, varying slightly with the age of the child: ℞. Tincturæ rhei, ℥iij.; magnesii carbonatis, gr. iij.; tincturæ zingiberis, ℥j.; aquam, ad ʒj. This is to be taken twice or three times daily, according to the effect on the bowels. Whether the rhubarb acts as a vermicide or simply by 'moving the worms on,' I am unable to say."

DE SENECTUTE.—To most people there is something peculiarly fascinating in a description of the habits and constitution of persons who have lived to extreme old age; even if the reader is not possessed by a secret hope that he may rival them in vitality, his imagination is stimulated by the history of men and women who were born in the last quarter of the eighteenth century, living on to witness the achievements, to share the sorrows, and, in their own persons, to afford matter for the scientific speculations of the last quarter of the nineteenth century. The series of fifty-two cases of reputed centenarians got together by the Collective Investigation Committee has been analyzed by Professor Humphry, of Cambridge, who is able to state positively that, in 11 cases, 2 males and 9 females, the evidence left no doubt that these old people were really centenarians. In the large majority of the cases the evidence was not conclusive, but there can at least be no doubt that all had attained to a very great age. Swift, in his "Voyage to Laputa," has given a description of extreme old age so appalling, and yet so nearly in accordance with everyday experience, that it is a pleasure to find Professor Humphry championing our common humanity, and describing centenarians who were cheerful, retained their faculties and their interest in relatives and old friends, and even showed a marked liking for making new acquaintances. The centenarian generally comes of a long-lived family, and is a person of active habits, both of body and mind, a good sleeper, endowed with a good appetite, and a tranquil, cheerful disposition. One centenarian collier had always drank as much as he could, and expressed his intention of continuing this habit, but all the others were stated either to have been moderate or very moderate in the indulgence of this taste, or to have been total abstainers. The majority also did not take tobacco in any form, but one chewed the drug, and seven, of whom four were women, smoked a great deal. Perhaps the most interesting fact which has come out of the analysis of these cases is that, though centenarians, as a rule, have not suffered much from illness during their long lives, yet a considerable number of instances were met with where even severe illnesses had been recovered from at an advanced age. Indeed, some of these old people seem to take a new lease of life, as the saying is, after passing four-score years, and are not only able to resist fresh attacks of acute disease, but even apparently to throw off some of the effects of chronic maladies from which they had been previously suffering. It is interesting to note that women are in a decided majority in Professor Humphry's list; after making every allowance for their comparative immunity from accident, exposure, and anxiety, and their greater temperance in eating and drinking, there still appears to be reason to believe that woman possesses a greater inherent vitality than man.—*British Medical Journal.*

MEDICINE IN TENNESSEE.—There are in Tennessee according to the "Medical and Surgical Directory of the United States," 2,059 persons claiming to be physicians and engaged in the practice of medicine. Of this number only 965 have diplomas, or any other authority upon which to establish their claims; hence 1,094 are practising without any authority whatever. It is but reasonable to suppose that very many of the latter class are wholly ignorant of even the principles upon which the science is based. This is indeed a bad showing, and it is to be hoped that a better day will ere long dawn upon our profession and the good people of Tennessee.—*Mississippi Valley Medical Monthly.*

TWO NEW REMEDIES FOR ULCERS.—The well-established hemostatic action of solutions of antipyrine prompted Dr. Bosse (*Berliner Klinische Wochenschrift*, 33, 1886) to employ it in a case of varicose ulcer, in which a profuse hemorrhage occurred from an arroded vein. He dusted the surface freely with antipyrine, and put on a compress of absorbent cotton and a bandage. After three days the dressing was changed, and the whole ulceration was found to be covered with healthy granulations. He therefore continued to apply the antipyrine for ten successive days, and thereupon dressed the granulations with a two per cent. ointment of nitrate of silver. The result was that the ulcer, which was as large as the palm of the hand, was healed in about three weeks. Thirty similar cases were treated with equal success. Bosse, therefore, recommends antipyrine as promoting the development of granulations in atonic ulcers and fistulæ. According to Martin, suppositories composed of cocoa-butter and ten grains of antipyrine afforded great relief in hemorrhoids and fissured anus, and may cure. Dr. A. Sydney Reynolds, in the *Medical News*, gives the result of his experience with sub-iodide of bismuth in the treatment of ulceration. Its therapeutic and physical properties may be summed up as follows: (*a*) It subdues the inflammatory process. (*b*) It substitutes the inflammatory regeneration of tissue with a neoplastic force, which closely simulates normal em-

bryonic histo-genesis. (*c*) It is, by its action, *a vital aseptic.* (*d*) It prevents the formation of pus. (*e*) It lessens direct and reflex irritability. (*f*) It is so bland and unirritating that it can be used on any surface. The sub-iodide of bismuth, by virtue of these properties, is almost a specific for ulceration.

Effect of High Altitudes on Heart Disease.—In the September number we gave an extract from a paper by Loomis, giving examples of serious consequences following the ascent of mountains by persons with cardiac affections. To offset this we quote from a private letter received from Dr. W. X. Sudduth, of the Medico-Chirurgical College, who is spending a year in the German laboratories, preparing material for his classes in histology. He writes as follows: "I have done some of the highest passes in Switzerland. I commenced with the Trutt pass (6,000 feet), and led gradually up to the ascension of the Stockhorn (12,000 feet). This latter trip, including the descent to Zermatt, kept me on my feet ten hours and a half. The ascent was over 7,000 feet, and the descent 9,000 feet. Pretty good day's work! Now, I know that this will be considered heroic treatment for a case of mitral stenosis. I have a theory, however, based upon my last year's experience, that it would be beneficial in my case, although such treatment is not laid down in the books. I held that as there were no vegetations in my heart, but only a lessening of the calibre of the valve, a high altitude, which would necessitate the expansion of the lungs would prevent pulmonary congestion, and also that if the continued exercise were not of too violent a character, the whole effect would be beneficial. So it has proven in my case. I have felt less uneasiness in the region of the left auricle than is customary with me. My general health is first-class, and my powers of endurance have not exceeded their present condition at any time in the last ten years."—*Medical World.*

Acute Fatty Degeneration of the Newly-Born.—Buhl, in 1861, described the symptoms and morbid anatomy of a rare disease, occurring in newly-born infants, to which he gave the name of acute fatty degeneration. His observations have since been confirmed by Hecker, Furstenburg, Roloff, and Runge, though it cannot be said that this condition is sufficiently well known for it to take its place as a well-defined and definite disease. The infants suffering from it are generally born in a condition of asphyxia, without obvious cause, and some die asphyxiated. If it survive it mostly suffers from more or less cyanosis, with hemorrhage from the bowels, stomach, or from the navel, on the separation of the cord. There is often jaundice, and blood extravasations take place beneath the skin, conjunctiva, or mucous membrane of the mouth; there may be general œdema; death usually takes place within two weeks. At the *post-mortem* minute hemorrhages are found in the various internal organs, sometimes they are infiltrated with blood; the tissues are bile-stained. On microscopical examination of the tissues of the heart, liver, kidneys, etc., they are found to be in a condition of fatty degeneration. The nature of the disease is quite unknown. It is interesting to note that a similar condition has been noted in newly-born pigs and other domestic animals.—*Providence Medical Journal.*

Winckel's Disease.—A somewhat similar disease as acute fatty degeneration of the newly-born has been described as occurring in an epidemic form by Winckel, and characterized by cyanosis, jaundice, and hæmoglobinuria. This epidemic occurred in the Foundling Hospital, at Dresden, in 1879, where twenty-three infants were affected in the course of a month. The symptoms noted were first of all a bluish tinge on the skin of the face, body, and limbs, with a more or less icteric tint; in some cases there was vomiting and diarrhœa. The urine was of a light-brown color, with a sediment consisting of epithelium and casts; the blood contained an excess of white corpuscles and many granular bodies. The symptoms mostly began on the fourth day after birth, death occurring in one case in nine hours, though the average duration of the disease was about two days. The sections showed a yellow staining of the skin and the internal organs. The spleen was large and hard, and dark red; the kidneys were usually dark brown in color, the microscopic examination showing their tubules to be filled with granular pigment. There were punctiform hemorrhages on the surface of the various internal organs, and fatty degeneration of the liver and heart.—*Providence Medical Journal.*

Linseed Oil in Pruritus.—A correspondent writes us that he has lately witnessed the triumph of linseed oil in the treatment of pruritus ani, and where all the classical remedies had failed. In the case of two patients, who had been for several years sufferers from pruritus ani, with a trifling erythematous eruption and no rectal complications that could be discovered, the free external use of linseed oil, at bed-time, about the parts gave immediate relief, and thus far free inunction with this simple remedy has given complete exemption from the nocturnal annoyance.—*Boston Medical and Surgical Journal.*

The Early Diagnosis of Vertebral Caries.—Dr. George W. Ryan, of Cincinnati, in a paper on this subject read before the Cincinnati Academy of Medicine, expressed himself as surprised that so many excellent observers should regard the knuckle as the first symptom of vertebral caries (*The Medical and Surgical Reporter*, December 11, 1886). Over-estimation of the importance of a diagnosis before the kyphosis is apparent, is impossible. If we believe that we have a constitutional disease, an essentially tuberculous one, beginning generally as a central ostitis of the body of the vertebra, the rational symptoms will be accordingly clear to us. It is now generally understood that this disease can be diagnosed in the incipient stage, and ought to be when the opportunity is presented. There are, however, cases which cannot be made out until the knuckle is visible. The first step is an accurate family history, directed especially to tuberculosis. The next, as to whether the child has passed through the infantile diseases or not, and as to convalescence. A tardy convalescence is often the starting-point of this disease. You will have heard before you ask it of a trauma, real or suspected. Further questioning will give you the history of restless nights, moaning and disturbed sleep, a tired feeling, or a continued desire for support. The child very likely complains of an epigastric pain, if it falls it screams from pain, it walks with care, or if young does not walk at all; that it holds its back very rigidly, or the shoulders thrown back to an abnormal degree, or one shoulder appears higher than the other, that it does not stoop, or if it does it is with great care. Pain in the back is occasionally complained of, and this generally when a jar is sustained. The gait is characteristic, almost pathognomonic. There is a carefulness, a rigidity about the spine which is never found unless there is spinal disease. The physiognomy will give you a pinched and anxious expression. The child can only stoop with the spine held rigid, or from pain gives it up. Physical examination, with all the clothing removed, may not give a trace of the angular curvature. Pressure to ascertain the existence of a soft spot is valueless. The examination as to mobility can be readily and painlessly made by having the child lie on its face and slowly bend the limbs with the opposite hand on the opposite side to the disease. It can thus be determined whether the column yields throughout, or whether there is any point where rigidity is present. If, with all this, rigidity is found, the diagnosis is unmistakable. In the cervical region the symptoms are altogether different. Torticollis is often present, with an occasional occipital or post-auricular neuralgia or hyperæsthesia. Brushing the hair causes pain; there is considerable interference with the act of motion, and the deformity is often slight. The acuteness of perityphlitis and peri-

nephritis would, as a rule, enable us to exclude spinal disease. The flexible spine would also assist. The pressure test, though of some pathological and clinical value, should, on account of its cruelty, be entirely discarded. He had never seen tenderness from pressure over a diseased spine in the incipient stages in but two cases, and in one of these it was probably neuralgic. It is indicative of a periosteal rather than a central lesion. To diagnose the kyphosis of rickets from caries, take into consideration the general rickety appearance of the child. He urged, in closing, the necessity of a physical examination, a clear history of the case, to keep in mind the pathology of the disease; and a diagnosis can readily be made, in the majority of cases, before the kyphosis appears.

Warts.—It is now fairly established that the common wart, which is so unsightly and often proliferous on the hands and face, can be easily removed by small doses of sulphate magnesia taken internally. M. Colrat, of Lyons, has drawn attention to this extraordinary fact. Several children treated with three-grain doses of Epsom salts, morning and evening, were promptly cured. M. Aubers cites the case of a woman whose face was disfigured by these excrescences, and who was cured in a month by a drachm and a half of magnesia taken daily. Another medical man reports a case of very large warts which disappeared in a fortnight from the daily administration of ten grains of the salts.—*The Medical Press.*

Diagnosis of Ovarian Tumors.—Professor J. S. Wellford, of Richmond, suggests as a valuable adjuvant means of differential diagnosis between pregnancy and ovarian tumors the examination of the phosphatic condition of the urine. In pregnancy, owing to the consumption of the phosphates by the fœtus, there is a very decided diminution of the phosphates in the urine. In the presence of ovarian or other tumors, owing to the strain on the nervous system by the disease, the quantity of the phosphates excreted is very largely increased.—*Practice.*

Ice-water enemata are used with success in the Birmingham General Hospital in cases of collapse often seen during diarrhœa in young children. It is claimed that one injection, two or three ounces, is very soon followed by sleep, and that, by the astringent effect on the congested vessels of the intestines, the diarrhœa is diminished. It is further claimed that no depression or other bad effect has resulted.

Hydrochlorate of quinine is combined with a smaller quantity of acid, and hydrochloric acid is better suited to the system than sulphuric acid. Hydrochlorate of quinine contains a larger proportion of the alkaloid quinine. While the price is one-third higher than the sulphate, yet its greater efficiency fully compensates for the enhanced value. Hence, says Mr. H. W. Fuller, the muriate of quinine is the best salt to use.

Ugly Vaccination-scars.—A writer in the *Correspondenz-Blatt für Schweizer Aerzte*, No. 18, 1886, who had a good opportunity of studying vaccination-scars at the Basle Federal Athletic Fête (*Turnfest*), draws attention to the æsthetic aspect of the "art of vaccination." Very many of the men had ugly, thick, and broad scars, reaching sometimes down to the elbow. When spoken to about the matter, they expressed indignation at the disfigurement inflicted upon them by the vaccinator. The writer recommends that more attention should in future be paid to this matter, which, though trifling in itself, may sometimes strengthen the hands of anti-vaccinationists. We understand that the practice of vaccinating on the leg is quite common among American physicians, and has much to recommend it.

Supernumerary Fingers among Negroes.—Dr. F. K. Stoekly, of Bluebank, states that supernumerary fingers and toes are found with extraordinary frequency among negro tribes living beyond the Orange Free States. He mentions the case of a Caffre, aged eighteen, who himself had six fingers on each hand; while the same anomaly was present in his father, in his mother, in his four sisters, and in one brother. His mother had also a double series of toes on both feet.

Bone-Grafting.—At the French Congress of Surgery M. Poncet expressed the belief that it would be possible to reconstruct a destroyed bone by means of osseous grafts. It is not after cicatrization that the grafting can be expected to succeed; it is at an anterior period, when active healing of the wound is taking place, that the grafting can be made under the most favorable conditions. M. Poncet then cited the case of a child, eleven years of age, from whom a long sequestrum of the tibia had been removed after osteo-myelitis. This sequestrum measured twenty-five centimetres in length. One month after the operation the first attempt at grafting was made. The fragments were taken from a newly born infant which had just died. Antiseptic dressing was used, and the limb was kept at rest with plaster splints. Twelve days later the dressing was changed; there was slight suppuration. New grafts, composed of four bony fragments, were then procured from a young kid. These were implanted in fleshy granulations and only one was eliminated. Six months after the operation there was a solid bony mass, thirty centimetres in length; the child became strong, and able to walk.—*Brit. Med. Journal.*

The Megaloscope.—At the French Congress of Surgery, M. Boisseau du Rocher exhibited a megaloscope, invented by himself for the purpose of exploring deep-seated cavities, such as the bladder, intestines, and stomach. By means of this instrument the mucous membrane of the bladder may be examined over an area of twenty-nine centimetres. It is fixed on a stem varying in shape and calibre, adapted to the cavities examined.

The Art of Washing the Hands.—In a communication to the Thurgau Medical Society, Dr. E. Haffter, of Trauenfeld, discusses the paramount importance of antisepsis in surgical and obstetrical practice; and, among other things, said that he is the best antiseptic-ist who best understands how to wash his hands, "since the latter are the most common vehicles of infection." The "art of washing hands" is not an easy one, according to the author. To insure absolute surgical cleanliness of the hands they must first be carefully washed with potash soap and water as hot as can be borne, and then with a five-per-cent. solution of carbolic acid, or one-per-mille solution of corrosive sublimate, or chlorine water.—*Brit. Med. Journal.*

Abdominal Tumors and the Excretion of Urea.—At the French Congress of Surgery, M. Thiriar, of Brussels, speaking of the analysis of urine in cases of abdominal surgery, stated that in benign tumors the proportion of urea in urine is always more than twelve grammes, while in malignant tumors there is always hypo-azoturia. In support of this opinion he mentioned several cases in which he was able, by this indication alone, to diagnose a tumor as benign or malignant, which was afterward confirmed by the operation, the necropsy, or the subsequent course of the tumor.—*Brit. Med. Journal.*

Some Statistics of Hernia.—Dr. Baxter's tables show that out of 334,321 recruits and substitutes examined by the recruiting officers during the War of the Rebellion, more than 17,000 were rejected on account of hernia. The London Truss Society, during the first twenty-eight years of its existence, issued over 83,000 trusses. Two factories in Philadelphia manufacture and sell from 216,000 to 250,000 per annum.—J. B. Hamilton, in *Chicago Med. Jour.*

A North Carolina Health Resort.—Tarboro', N. C., is said to be gaining quite a reputation as a resort for consumptives. The local physicians claim that phthisis is unknown in the neighborhood.

Original Lectures.

MULTIPLE NEURITIS AND ITS RELATION TO CERTAIN PERIPHERAL NEUROSES.[1]

BY M. ALLEN STARR, M.D., PH.D.,

PROFESSOR OF NERVOUS DISEASES, NEW YORK POLYCLINIC.

LECTURE II.

MR. PRESIDENT, LADIES AND GENTLEMEN OF THE PATHOLOGICAL SOCIETY:

IN the last lecture we studied the history of multiple neuritis, and incidentally obtained some clinical pictures of various forms of this disease. We also discussed its pathology and its etiology. This evening we must look more carefully at the symptoms presenting themselves in the different varieties of the affection.

An etiological classification of the cases of multiple neuritis appears to be the one most useful to the clinical observer, and as the forms vary considerably in their symptoms, we shall perhaps arrive at a more definite knowledge of the disease if we consider each of the classes separately. It is possible to distinguish—

1. Toxic cases, due to poisoning by alcohol, arsenic, lead, and bisulphide of carbon.

2. Infectious cases, due to the direct action upon the nervous system of the infectious agents, producing diphtheria, variola, typhoid and typhus fevers, severe malarial fever, and tuberculosis; to which must be added the agent causing the epidemic form of neuritis known as kakke or beriberi.

3. Spontaneous cases, due to uncertain causes, among which cold, and exposure to damp and wet, and to overexertion, may find a place.

I. TOXIC CASES.—(*a*) *Multiple neuritis, due to poisoning by alcohol.* While alcoholic paralysis has been universally recognized for many years, it is only within a short time that the symptoms and pathology have been brought into a logical connection. It is to Moeli,[2] of Berlin, and Dreschfeld,[3] of Manchester, England, that we owe the most important recent contributions to the knowledge of this form of neuritis, though the work of Henry Hun,[4] of Albany, and of Bernhardt,[5] of Berlin, cannot be passed over without recognition.

It will be remembered that among the first cases of multiple neuritis in which an autopsy was made, viz., those of Lancereaux,[6] the disease was traced to alcoholism. Lancereaux deserves the credit of demonstrating the pathological basis of alcoholic paralysis, for the descriptions of its symptoms previously given by Jackson and Huss were not accompanied by post-mortem records. But Lancereaux's observations were for many years overlooked by physicians outside of France; and in England, where the disease is well known, it was ascribed, as lately as in 1883, to a spinal lesion.[7] But in 1884 Dreschfeld combated this theory and called attention to its true pathology, showing that cases formerly supposed to be spinal paralysis were really due to an affection of the peripheral nerves.

All observers have emphasized the fact already noted by Jackson, that the disease is especially frequent among females. Males are not, of course, exempt from alcoholic paralysis, but in them the poison seems more liable to manifest itself by acute cerebral symptoms than by those of disease of the peripheral nerves. It is especially frequent among those persons in the higher classes whose nervous organism is highly developed, and who lead a comparatively inactive life. It seems not at all improbable that sedentary habits predispose an alcoholic drinker to this disease, and hence active workers, male or female, though taking an equally large amount of liquor as the luxurious drinker, escape. All alcoholic drinks are not equally prone to produce paralysis. It is the spirituous liquors—brandy, whiskey, gin, and rum, and the liqueurs, absinthe, vermouth, etc.—which are dangerous. And it is only after these drinks have been consumed in large amounts and for a considerable length of time that neuritis develops. Its onset, though often apparently very sudden, is usually gradual. For months the patient has suffered from chronic gastritis, insomnia, general neuralgic pains, or severe pains in the joints or limbs, and from tremor and a certain feebleness in movement, when all at once her legs give way beneath her, and after the sudden fall she finds herself unable to rise. Thus a patient of my own, after a year of such premonitory symptoms, was seized with paralysis quite unexpectedly when getting out of bed in the night. This paralysis soon becomes complete in the feet and legs below the knees, and may advance up the thigh. It next attacks the hands and forearms, and while in all extremities it is often greater in the extensors than in the flexors, in some cases both groups of muscles become entirely helpless. This has been the case in three patients under my care. The paralyzed muscles are flabby and soon become atrophied, they have no excitability to mechanical irritation, and the tendon reflexes are lost. They fail to react to a faradic current in the majority of cases, though occasionally a very strong current may produce a response. When galvanism is applied the reaction of degeneration is found to be present. No stimulus can be given to the muscle by sending a current through its nerve, and the positive pole produces more marked contractions with an equal current than the negative pole when placed on the muscle, and then it is only a slow or vermiform movement, not the quick jerk of health. It is also found that strong galvanic currents have to be used to produce any contraction at all. The paralysis of the muscles may advance rapidly in severe cases, involving the motor cranial nerves, the muscles of the trunk, and lastly the diaphragm, thus causing death. More frequently, however, it is arrested when only the distal parts of the extremities are involved, and then it gradually subsides until recovery is complete. The position assumed by the paralyzed limbs has been thought to be almost characteristic. There is dropped wrist quite similar to that seen in lead-palsy, and also dropped foot, due to the falling forward of the foot from its own weight, since the anterior tibial muscles are weak. This deformity is increased by the fact that the patients lie in a recumbent posture with the feet extended; and when the flexors of the toes are but slightly affected, as sometimes is the case, their unopposed contraction serves to exaggerate the malposition. If there is entire paraplegia the legs

and thighs may both be extremely flexed, so that the heels touch the buttocks, but this is exceptional. While the dropped wrist is the usual deformity of the hands, cases are recorded in which the paralysis was limited to single muscles and to muscles supplied by single nerves. Thus Lilienfeld describes a weakness of the extensors of the thumb, fourth and fifth fingers, and Leudet mentions a paralysis of the ulnar nerve. In one case of my own the *main en griffe* was the deformity noticed, indicating a weakness of the interossei only. Such cases as those of Hun,[1] where a facial paralysis was seen, or of Lilienfeld,[2] where double abducens paralysis occurred, are certainly rare, and still more so are those in which irregular, rapid pulse has been ascribed to an affection of the pneumogastric.

To the physician these motor symptoms, and the œdema, occasional lividity, profuse sweating, and glossy skin, so often associated with them, are very noticeable. But the patient suffers far more from the disturbances of sensation. In the description of Jackson, the pains were graphically portrayed. They are the cause of terrible agony, sufficient to produce insomnia, and wearing seriously upon the endurance of the sufferer.

In addition to pain, hyperæsthesia is not infrequently observed. It is usually quite extensive in the legs, though in cases of poisoning by absinthe it has been limited to the soles of the feet. The muscles, as well as the skin, are sensitive to handling and to pressure, and marked tenderness in the course of the nerves is always elicited by examination. In one of my cases soon after the onset, the patient could not bear to be touched or moved, though perfectly unable to help herself. Charcot goes so far as to say that muscular sensitiveness associated with flaccid paralysis is pathognomonic of alcoholism.

Paræsthesiæ are always complained of. Numbness, tingling, and formication are frequent. In one of my patients the sensation was as if heavy bracelets were around the wrists, and as if very tight drawers were on the legs. At other times she felt as if the limbs were swollen and as if the skin were about to burst. Such sensations may cease as the case increases in severity, and give place to a total lack of sensation in the parts. They return, however, with advancing recovery, and are among the last symptoms to disappear.

Abolition of tactile sense, and to some degree of muscular sense, is the rule after the paralysis is developed. Temperature-sense and the perception of pain are never wholly lost, but may be delayed in transmission. The anæsthesia may be limited to irregular areas, and may be only in the cutaneous distribution of one nerve, but is usually found over the entire distal part of the paralyzed limb. Usually the cutaneous reflexes are preserved. The loss of muscular sense is, in some cases, so marked a symptom, and one of such early occurrence, that Dreschfeld distinguishes a class of cases which he terms ataxic rather than paralytic. And this distinction is perfectly justifiable, for in many cases it is the inco-ordination which attracts the attention of both the patient and the physician. It is this class of alcoholic cases which may be mistaken for locomotor ataxia, and which have been named by French writers pseudo-tabes alcoholique.[3] But ataxia is not exclusively limited to this class of cases. It may be present in some degree in cases of paralysis, and during recovery from paralysis the deficiency in co-ordinating power may become evident, and appear to retard the progress of the case. Nor are the cases of ataxia, on the other hand, free from paralysis.

And this fact is proven by the observations of Westphal[4] and Charcot. For, by contrasting the walk of a true ataxic patient with that of an ataxic alcoholic patient, they have each discovered several points of difference. The ataxic patient throws the foot forward with undue violence, the toe lifted high in air, and brings first the heel down forcibly and then the entire foot. The alcoholic, however, has some weakness in the muscles of extension and cannot raise the toe. He therefore lifts the foot high in order to step over the hanging toe and not to trip on it, but the motion is made without undue force. He then throws the foot forward in order to throw the toes up and get them out of the way as he brings the foot down to the floor. The motion is awkward and has an appearance of one stepping over high obstacles, but it is a voluntary attempt to remedy a deficient power—not the involuntary awkwardness of a man unable to manage strong muscles. There may be in both patients some tottering, and swaying when standing with the eyes closed, the so-called Romberg symptom, is common to both locomotor ataxia and alcoholic neuritis. Dejerine describes the following case, in which the symptoms resembled those of tabes.

Observation VIII.—Male, forty-two, a hard drinker, complained for four months of shooting pains in the legs, and noticed a gradually increasing difficulty in walking, which was worse in the dark. He had also found his feet swollen at times, and had some difficulty in micturition. Examination on admission to the hospital showed a high grade of ataxia in walking, Romberg's symptom, loss of tendon reflexes, anæsthesia almost total of entire body, considerable analgesia with retardation of sensations of pain, temperature-sense being preserved, and loss of muscular sense in the legs. The muscles were slightly feeble and a little diminished in size. It could hardly be said that there was paralysis or atrophy. The diagnosis made was locomotor ataxia of an unusual type. The onset was so rapid, the anæsthesia so extensive and severe, the paresis of the limbs, though slight, so evident, that it differed from a typical tabes. But no other diagnosis could be made from the symptoms. The patient died of chronic nephritis six weeks after admission. The autopsy showed the spinal cord to be normal. But in the cutaneous and to a less degree in the intra-muscular branches of the nerves, as well as in the distal parts of the nerve-trunks, a high grade of parenchymatous neuritis was found. The nerve-tubes had lost their double contour, the myelin sheath was segmented, the protoplasm was increased, the nuclei multiplied. The nerve-trunks on the plexuses and the nerve-roots were normal. The nerves of the legs were more deeply involved than those of the arms.[1]

The second case, in a female forty-nine years of age, presented almost identical symptoms and lesions.

The special senses are occasionally affected in cases of alcoholic paralysis. Amblyopia has been observed, and also defective vision from central scotoma. The field of color-vision is often contracted, even when sight is preserved. There may develop a true optic neuritis, evident to the ophthalmoscope, and this may go on to optic-nerve atrophy.[2] Inequality of the pupils is frequently seen, as is also a moderate contraction of the pupil. All these eye symptoms, occurring as they may in a case of the ataxic variety, make a differential diagnosis from locomotor ataxia difficult. The Argyle Robertson pupil (which contracts in accommodation but not to light) has not been seen in alcoholic cases, while it is an early symptom of tabes.

One feature of alcoholic paralysis remains to be noticed, viz., the cerebral symptoms. These are hardly ever wanting. There is at first the excitement rising to the degree of active delirium, with illusions and hallucinations of the various senses; there is the insomnia which so soon exhausts the patient if it is not remedied; there is the loss of memory, especially of recent occurrences; and the lack of power of attention or concentration which prevents intelligent conversation. The indifference to

bodily wants may be so great as to lead to uncleanliness, and since paralysis of the sphincter is the rare exception, incontinence is usually to be ascribed to the mental state. It is useless to attempt to get any reliable history of their illness from these patients. Their statements are unintelligible or unreliable. And here it may be well to notice a symptom first remarked by Strümpell.[1] These patients will relate occurrences as having happened recently with much elaboration of detail, when as a fact the story is entirely a product of their imagination. Thus one patient of my own, who had been confined to bed for many days, told me one afternoon that she had been out to see an eminent gynecologist during the morning; had gone to his office and waited for him several hours; had seen other patients there, and finally had been told by the doctor's brother that he would not return in time to see her, so she had come home again. And this was all related in apparent good faith, so that I have no doubt that she believed that what she said had occurred. With the possibility of such delusions in view, it is evident that the statements of these patients cannot be accepted regarding anything, especially as to their own history.

One patient, who was admitted to Bellevue Hospital during my service there, told me a different history of her case every day for a week, and it was only by interviewing her friends that the correct account was obtained.

The course of alcoholic neuritis is quite uniform. After a sudden onset the symptoms rapidly advance to a high degree, which is reached in a week or two from the beginning of the paralysis or ataxia. Then they may increase further, and cause death by respiratory paralysis. Usually they remain stationary for a time, and then gradually subside, the entire duration being from two months to a year. Individual muscles regain their power, tone, firmness, and electrical reaction slowly, and during recovery the tingling and numbness in hands and feet may be severe. In a few cases the muscles become contractured, and permanent deformities, only to be overcome by long-continued massage or by operative measures, develop. When the fact is considered that those who recover rapidly rarely fail to resort again at once to the use of stimulants, and thus expose themselves to the danger of a relapse, the ultimate fate of the chronic cases is hardly more serious than that of those who get well.

As examples of the paralytic form the following cases are cited:

Observation IX.—A baker, aged forty-seven, phthisical, a moderate drinker, had suffered for several years from numbness of the hands and legs; and for a year before the acute invasion of his illness from a slight weakness of the legs and uncertainty of motion in walking. This weakness became much worse during the spring of 1881, so that all summer he was confined to his room, though he managed to walk a little. In November, after an uneasy night, during which he was delirious, it was found that he could not move his legs at all, and that his arms were powerless. He was brought to the hospital November 25th, when a total paralysis, with atrophy and loss of tendon reflexes, was discovered in legs and arms, as well as slight disturbances of sensibility in the legs, consisting of a delayed sensation of pain. His mental condition was a weak one, but he answered questions rationally. The face was in no way affected. No involuntary evacuations. Electric examination showed a great diminution, and in many muscles total loss, of faradic excitability when the current was applied both to nerve and to muscle. With the galvanic current few contractions could be elicited by exciting the nerves, and by exciting the muscles the slow contractions characteristic of RD,[2] as well as the predominance of AnCC over KCC were present. The mechanical excitability of the muscles was not impaired. There were no pains. During the following three months there was little change in the condition, except that his mind was not clear, and that he told extraordinary stories of having been out walking, of having made purchases, etc., when, in fact, he could not move from the bed.

His pulse became more rapid during this time, averaging 120 per minute. In February, 1882, the legs had become œdematous, and there was marked analgesia in them, except on the soles of the feet, which were hyperalgesic; sensations of touch were, however, readily perceived. Though he had a sanguineous dysentery, there was no incontinence. On the 12th there developed suddenly great difficulty in respiration, due to suspension of all diaphragmatic breathing, and the next day he died. An ophthalmoscopic examination on the last day showed an atrophy of both optic nerves on the outer side of the eyes.

Autopsy: Brain and cord normal. No macroscopic changes in the nerves. A microscopic examination, however, showed the presence of a very high degree of degeneration and degenerative atrophy in the nerve-fibres. The myelin had divided in large and small drops, containing fat-granules; the degenerated mass within the Schwann sheath, consisting of myelin and axis-cylinder, was seen in various stages of absorption, and in spots the empty Schwann sheath alone remained. No inflammatory exudation was present, and the endoneurium and perineurium appeared to be normal. The muscles showed evidence of degenerative atrophy. The anterior nerve-roots were normal.[1]

The lesion here resembled exactly that in Joffroy's case, already cited. It was similar in the following case:

Observation X.—Female, who had recently indulged in alcoholic excesses and had suffered from gastritis and delirium tremens; complained for some days of pain in her legs and numbness in hands and forearms. When seen by Dr. Webber the pains in the limbs were severe, and she could not turn in bed without help, her knees were drawn up, and attempts to straighten them caused pain. There was loss of power in extensors of the wrist and hands, and the fingers could not be shut perfectly. There was general tenderness over the muscles of the extremities, and pressure along the nerves was very painful. Her throat was sore, but she did not have diphtheria. She spoke in a whisper and with difficulty. Three days later anæsthesia of the feet and hands appeared, and the tendon reflexes were lost. The pain became so severe that morphine was given to control it. The paralysis became more complete, the anæsthesia increased, incontinence of urine and fæces developed, she appeared to be very feeble, and respiration became wholly thoracic. Seventeen days after admission to the hospital she died.

Autopsy showed brain and cord normal. The chief nerve-trunks of the extremities, and the phrenic and pneumogastric, were in a condition of degeneration, the distal ends being affected to a greater degree than the central portions. "The simplest change found was in the medullary sheath at Ranvier's constrictions, without break in the axis-cylinder, and without increase of nuclei." In some nerves extensive degeneration was found, the medullary sheath being broken up into fatty fragments, the axis-cylinder discontinuous or destroyed, and the number of nuclei increased. In the fibres which were most altered was found an increase of nuclei; and apparently small masses of protoplasm, not nuclei, were tinted in the midst of the granular débris. Nearer the root of the nerves axis-cylinders were more numerous. In the sciatic the sections from the highest part of the nerve, which had been preserved, were still diseased in a small proportion of their fibres.[2]

A very similar case, with the same changes in the nerves, is recorded by Müller.[3]

[1] Strümpell: Arch. f. Psych., 1883, xiv., 339.
[2] RD = reaction of degeneration; AnCC = anode closure contraction; KCC = cathode closure contraction.

[2] S. G. Webber: Arch. of Med., 1884, xii., 33-49.
[3] F. C. Müller: Arch. f. Psych., 1883, xiv., 3.

The following case, under my own care, terminated favorably :

Observation XI.—Male, aged thirty-six, a hard drinker, after an attack of gastritis became paralyzed suddenly in both legs. A few days after this, both hands became useless, so that he was completely helpless. His wife says that his memory is quite gone. On admission to Bellevue Hospital, September, 1880, seven weeks after the onset, he complained of pain in all four extremities, and of tenderness in the muscles and joints when these were handled. The upper extremities were almost totally paralyzed below the elbows, the only motion possible being a slight flexion of the fingers. There was wrist-drop on both sides. The lower extremities were totally paralyzed below the knee, and the feet hung down motionless. The muscles of the thighs were also affected, for although he could pull his legs up in bed, it was with great difficulty that they could be straightened out. All the paralyzed muscles were atrophied, and the faradic reaction was lost in the extensors and greatly diminished in the flexors. The galvanic reaction was not tested by me from lack of apparatus. Tactile sense was considerably impaired, but the senses of pain and temperature and muscular sense seemed to be natural. The knee-jerks were lost. When an attempt was made to have him stand, the feet were pushed out and the knees doubled under him at once. Fibrillary twitchings were very noticeable in the atrophied muscles, and a marked tremor of the tongue was seen. The facial and ocular muscles were not affected, and the special senses were normal. There was no incontinence of urine and no symptom of thoracic or visceral disease. His mind was much impaired. He talked in a rambling manner, laughed much, could not fix his attention, and his memory was so poor that no reliance could be put in his statements. Under treatment by iodide of potash, and complete cutting off of all stimulants, he began at once to improve. In two months from the time of admission he was able to walk, and one month later he was discharged perfectly well.

These cases are sufficient to present a clinical picture of the symptoms and course of the forms of alcoholic multiple neuritis. The differential diagnosis, elements of prognosis, and means of treatment will be considered when other classes of the disease have been studied.

(*b*) *Multiple neuritis due to poisoning by arsenic.*[1]—It has long been known that an occasional result of arsenical poisoning is the development of paralysis, but it is only within the past four years that the fact has been determined that the symptoms in these cases are due to an affection of the peripheral nerves. Had the fact of the peripheral origin of alcoholic paralysis not been already proven, it is probable that the theory so long in vogue, that arsenical nervous symptoms were due to spinal lesions, would still prevail. But there is such a similarity between the two sets of cases, that it is impossible to ascribe them to other than the same pathological condition. Autopsies in support of the position that the peripheral nerves are involved are few in number, but in several cases the lesion has been found. The observations on record of spinal lesions are, it is true, more numerous; but when these are compared it is found that different lesions have been discovered in different cases, so that there is no single pathological change in the spinal cord which is constantly produced by arsenic. Further, some of the changes described in experimental cases in animals (viz., vacuolization of cells) are due to imperfect hardening of the specimens. It must, therefore, be admitted that multiple neuritis may be due to arsenical poisoning.

The changes produced in the nerves are so exactly similar to those already described, that there is no need of a recital of the pathological process.

The nervous symptoms produced by arsenic have been thought to vary somewhat, according as the ingestion of the poison has been a sudden or a gradual one. Brissaud claims that if there is slow poisoning, as, for example, by the long-continued use of Fowler's solution, paralysis is rather the exception, and is not severe, it is diffuse and transient; while other symptoms, such as gastro-enteritis, trembling, delirium, and aphasia attract the chief notice. If there is acute poisoning from an overdose of arsenic, he holds, on the other hand, that paralysis ensues either during the period of active symptoms of poisoning, or soon after. The observations of other equally careful authors do not entirely support this view of Brissaud; for in two cases of Dana, one of acute, the other of chronic poisoning, very similar symptoms of paralysis and ataxia developed.

The description which has been given of alcoholic paralysis might almost be repeated for arsenical paralysis. There is the same limitation of the affection to the muscles of the distal parts of the extremities, the extensors being chiefly affected, and the weak muscles are flaccid, soft, and atrophied. There is a partial reaction of degeneration. The tendon reflexes are abolished; skin reflexes are preserved. There is often a marked tremor. The paralysis may begin either in the feet or in the hands, is usually bilateral, but has been in four cases of the hemiplegic type. The same dropped wrist and dropped foot are seen as in alcoholic cases. Disturbances of sensibility are prominent symptoms; burning, tearing, shooting pains; formication, tingling, muscular, and arthritic pains and tenderness are associated with hyperæsthesia, and this may be followed by irregular patches of anæsthesia. The muscular sense is usually impaired, and so much so in some cases that an attempt has been made to establish a distinct class of cases as arsenical ataxia, or pseudo-tabes arsenicale. In these cases the inco-ordination of hands and feet, Romberg's symptom, and an awkward gait are very noticeable, so that tabes may be suspected until the history makes the causation evident. In a case of Dana's the patient could not tell the position of his limbs or distinguish between weights differing one to forty. In Scolozouboff's case the walk resembled that described by Westphal in alcoholic tabes, and was easily distinguished from a real ataxic gait. Seeligmüller and Dana, however, affirm that the gait in their cases was like that of locomotor ataxia. Occasionally œdema of the extremities, cyanosis, unusual sweating, and extensive desquamation indicate an implication of vaso-motor and trophic nerve-fibres. In the most severe cases contractures in a flexed position developed in the paralyzed limbs. The sphincters are never involved. The duration of arsenical paralysis is somewhat greater than that of ataxia. Either condition may last several months, but occasionally the recovery is complete in a few weeks. Frequently, after the power has returned, the patient suffers for months from numbness and tingling in the extremities, which is sufficient, as in a case under my own observation, to interfere with the finer motions, to disturb the sleep and cause constant discomfort. According to Gerhardt's statement (cited by Dana), ninety-seven per cent. recover wholly.

(*c*) *Multiple neuritis due to poisoning by lead.*—It is not my purpose to enter upon any description of the various forms of lead palsy, which are familiar to every practitioner. Nor is this the proper place for a discussion regarding the various theories of the pathology of the disease. It is only necessary to call attention to the fact that there are now on record a number of autopsies in cases of lead paralysis in which the lesion has been found in the peripheral nerves. In a recently published case of Schultze[1] there was found a very marked atrophy and disappearance of nerve-fibres in the trunk of the

musculo-spiral nerve, below the point where the branch to the supinator longus was given off. This decreased in intensity centrally, so that at the brachial plexus no anomaly was found. It increased in intensity toward the termination of the nerve in the muscles. The spinal cord was normal. This is simply a type of a number of recently published cases. On the other hand, there are numerous cases of this disease in which decided spinal lesions have been found—so numerous that many writers always ascribe the disease to destruction of certain groups of cells in the anterior cornua of the spinal cord. It must be admitted, therefore, that in lead we have a poison which, under certain circumstances, affects the spinal cord, and under other circumstances produces neuritis. It may be claimed that the same is true of alcohol and arsenic, and in showing that these poisons can cause neuritis there is no intention of defending the position that they never affect the central nervous system. But it is important to notice that the central organs are rarely involved. The limitation of the neuritis in lead palsy to the motor nerves makes the clinical picture in some cases resemble closely that of spinal disease. In illustration of this the following case is cited:

Observation XII.—A male, aged thirty-six, by occupation a dyer, had suffered from numerous attacks of lead colic, followed by general muscular weakness, which on one or two occasions was so great as to be a general paralysis rather than a simple weakness, and had finally developed a paralysis of the extensors of arms and legs, when admitted to the hospital, where he spent the last three years of his life. During this time his paralysis varied somewhat in degree, but was never entirely recovered from. The muscles affected were the extensors of arms and legs. These were much atrophied, and showed a loss of faradic reaction, and a characteristic change in the galvanic reaction, the anode producing stronger contractions than the cathode, and all contractions being slow. There was also a considerable degree of œdema in the extremities, especially in the legs. Spasms in the unparalyzed flexors occurred on one occasion for one day. The patient suffered also from the symptoms of cardiac disease and phthisis, to which he finally succumbed.

The autopsy showed no changes in the brain or spinal cord. The muscular branches of the peripheral nerves, although presenting no macroscopic changes, were found in a state of extreme degeneration when examined microscopically. Side by side with normal fibres were to be seen fibres, unstained by osmic acid, wholly destitute of myelin sheath. There was no fatty degeneration. Between the fibres a thick, finely fibrillary connective tissue, with small cells, was found. Transverse sections of the nerve-trunks showed a large number of small fibres scattered among the normal fibres, but not collected into bundles, and it was often difficult to distinguish naked axis-cylinders from connective-tissue fibres. The lesion was an increase in the connective tissue of the endoneurium with simple atrophy of the nerve-fibres of different grades.[1]

But in a certain proportion of the cases of lead palsy there are marked sensory disturbances, consisting of severe pains, and anæsthesia, with numbness. In these it is possible, especially if tenderness along the nerves and in the muscles is present, to make the diagnosis of multiple neuritis. The history of the following case, under my care, coincides so closely with that of other toxic cases of neuritis that the diagnosis could not be mistaken.

Observation XIII.—Male, aged thirty-eight, after suffering from an attack of lead colic, began to feel numbness and pain in his legs and feet, which soon extended to his hands and forearms. This steadily increased for two weeks, and to it was added paralysis of the extensors of both hands and both feet, so that at the end of that time he was unable to use his hands or to stand. With the paralysis there was a rapid atrophy of the muscles, and a decline in the faradic excitability. The muscles became more and more tender, and the spontaneous pains gradually increased until it was necessary to use opium freely to quiet them. By the end of a month a well-marked anæsthesia had developed below the knees, and it was noticed that the atrophied muscles were in a constant tremor. There was wrist-drop and foot-drop on both sides, and all reaction to faradism ceased. It required a very strong galvanic current to produce contraction, and ACC was greater that KCC. The knee-jerk was preserved. The muscular sense was impaired. For five months his condition remained stationary, in spite of treatment by strychnia, iodide of potash, massage, and electricity. Then a gradual improvement set in, the pains became less severe, sensation returned, the muscles regained their contour and strength, and finally the electric contractility returned to the normal standard. About a year from the onset of the symptoms, the recovery was complete.

(*d*) *Multiple neuritis from poisoning by sulphide of carbon*[1] *and from illuminating gas* has been suspected, and the similarity of the symptoms in such cases to those already described is quite remarkable. But as there are no autopsies to substantiate the theory, this cause is merely mentioned.

II. Multiple Neuritis consequent upon Infectious Diseases.—There are a number of infectious diseases which are especially liable to be followed by the development of nervous symptoms. These are diphtheria, variola, typhoid, typhus, and scarlet fever, malarial fever, and tuberculosis. The nervous affection usually appears shortly after the period of convalescence in the acute fever. The disease may consist of a simple paralysis of the muscles in the region of distribution of a single nerve. It may affect several nerves on both sides of the body symmetrically. It may even paralyze two or more limbs. It occasionally produces sensory as well as motor symptoms in a single nerve-trunk. It may even cause a general sensory and motor paralysis of as widespread and complex a kind as that produced by chronic alcoholism. Sometimes the symptoms are chiefly of a sensory kind, and consist exclusively of pains, numbness, and anæsthesia, or hyperæsthesia, in the legs, or of a loss of the muscular sense, in which case a true ataxia is the most noticeable symptom. Thus it is evident that the poison of an infectious disease may act as powerfully upon the nervous system as any other form of poison known.

It is only since the clinical pictures presented by multiple neuritis have been recognized that a question has arisen as to the part of the nervous system affected in these cases. Formerly all such phenomena were referred to central lesions; and undoubtedly in many cases this was justified, since autopsies are not wanting to prove that anterior poliomyelitis, diffuse myelitis, and hemorrhages into the cord and brain may follow the acute fevers. There are, however, many conditions which do not correspond to the types of disease produced by central lesions and which recover with a rapidity impossible were the brain or spinal cord involved. It was these cases which raised the question of some possible affection of the peripheral nerves. And careful investigation has been rewarded by the actual discovery of lesions in them.[2]

(*a*) Diphtheritic paralysis is probably more common than any other of these forms of neuritis. As is well known, it is usually the soft palate to which the paralysis is limited, and as a result difficulty in swallowing and in speech are the most prominent symptoms. Bernhardt has found[3] that in the large majority of cases of this kind there is a loss of the patella tendon reflex, but whether this indicates any general affection of the peripheral nerves he does not venture to state. The limitation of the

[1] Ross: Medical Chronicle, January, 1887.

[2] Pitres et Vaillard: Rev. de Médecine, 1885, p. 986; 1886, p. 193 et p. 574, Des Névrites Périphériques chez les typhoïdes, les tuberculeux et les tabétiques; also, Arch. de Neurol., 1886, p. 337, De la névrite segmentaire.

[3] Virch. Archiv, 1885, Bd. 99, s. 393.

paralysis to the palate has been explained by supposing that the poison of the disease has a direct action upon the terminal filaments of the nerves, which in this position are, as it were, dipped constantly in the poison. This theory is supported by a case in which paralysis of the abdominal muscles was associated with diphtheritic inflammation of the navel in a new-born child. But the more serious cases prove that through the blood the poison may be carried to nerves far removed from the seat of the diphtheritic inflammation.

And the following cases demonstrate the wide-spread symptoms which such general poisoning can produce, as well as the nature of the lesion.

Observation XIV.—Marie S——, aged thirteen, after suffering for a few days from a slight sore throat, found herself unable to see clearly because of the development of a paresis of accommodation. There followed a slowly progressing ataxia of the upper, and later of the lower, limbs, with uncertain gait, disturbance of touch, pain, temperature, and muscular senses, with delayed sensation of pain and loss of tendon reflexes. At first she felt shooting pains in the limbs, but later these ceased. There was at no time tenderness of the nerves to pressure. After three months bulbar symptoms appeared, atrophy, with paresis of the tongue, difficulty in swallowing, spasms of coughing, weakness of voice, and paralysis of the palate. The muscles of the hands began to atrophy about the time that the bulbar symptoms commenced, and soon were useless. In the atrophic muscles the faradic reaction was absent, the galvanic much reduced, and very slow. Nine months after the onset she died of pneumonia.

The autopsy showed the brain and spinal cord to be normal. In all the peripheral nerves of the extremities, as well as as in the hypoglossal and recurrent laryngeal nerves, well-marked atrophic degeneration was found, with destruction of axis-cylinders and medullary sheaths, and with thickening and increase of nuclei in the connective-tissue sheaths.[1]

Observation XV.—Male, aged seventeen, after an attack of diphtheria grew gradually weaker and weaker, developed paralysis of the uvula and paralysis, with some atrophy, in the muscles of all the limbs, and a slight paralysis of the face and tongue. There was no real ataxia, the muscular sense being normal, but the weakness of the muscles interfered with all accurate movement and caused trembling. The eyes were not affected. There was a slight decrease of tactile sense all over, but pain-sense was slow and imperfect. The reflexes were lost, electric reaction was normal in all muscles except the palate, in which RD was found. The sphincters were unaffected. The paralysis involved the respiratory muscles three weeks after the onset of the disease, and caused his death.

The autopsy showed extensive parenchymatous neuritis in all the peripheral nerves. The various stages of degeneration were found side by side in many nerves, and all degrees of degeneration were discovered. The nerves of the extremities, as well as the phrenics, showed these changes. Some nerve-fibres had simply lost their myelin sheath, others were reduced to a series of granular corpuscles; others consisted only of the empty Schwann sheath, whose nuclei were numerous. In many nerves the lesion only involved a few segments, and was not continuous through the entire length. At places circumscribed thickening of the endoneurium produced nodular appearances in the course of the degenerated nerve. Here congestion and emigration of leucocytes were found. The perineurium was unaffected. In almost all the muscles of the extremities and trunk such degenerated nerve-fibres were found. The cutaneous nerves were similarly affected, but to a less degree. The nerve-trunks were but slightly affected, as were also the nerve-roots. The spinal ganglia and cord were normal.[2] The limitation of the degeneration to single segments has also been noticed by Gombault and by Pitres et Vaillard.[1]

Observation XVI.—A boy, aged eight, developed paralysis of the soft palate one week after an attack of diphtheria. This continued for one month, when there suddenly appeared a weakness of all the extremities, and some disturbance of sight. Examination of the eyes showed a complete paralysis of all the recti muscles, with double ptosis, the accommodation and pupil reactions being preserved. The right side of the face was paretic. There was a very marked ataxia in all the limbs. It was with difficulty that he could carry food to his mouth, and he walked with much staggering, and with legs wide apart. Power and nutrition of the muscles was normal, and there was no change in their electric contractility. The tendon reflexes were absent, but the skin reflexes were preserved; and there was no disturbance of sensation or of bladder and rectal functions. The symptoms all increased for ten days, and then respiratory paralysis caused his death.

It was possible to examine the brain only. The small vessels and capillaries were engorged, and the perivascular spaces full of emigrated corpuscles, while here and there small capillary hemorrhages were found. The vessel-walls were not affected, and there were no thrombi discovered. The nuclei of the cranial nerves showed no changes. Both oculo-motor nerves were the seat of very great changes. The myelin sheath of individual nerve-fibres absorbed the carmine stain. In many fibres no axis-cylinder was to be seen. In others the cylinders were swollen or atrophied, presenting variations in size. The number of nuclei of the endoneurium was greatly increased, and among them large granular corpuscles were discovered.[2] The lesion, therefore, which had caused the ocular paralysis was a diffuse neuritis.

A similar affection of the ocular muscles, associated with general weakness, has been reported by Utthoff,[3] which developed two weeks after an attack of diphtheria in a boy, ten years of age, and who at the end of three months had completely recovered. In this case all reaction of the pupils in accommodation was lost, but the light reflex remained. The eye symptoms were attended by some paresis, especially in the legs below the knees—but the muscles were not atrophied, nor was their electric contractility altered. There was a very marked tenderness along the course of all the nerve-trunks. After recovery was complete the knee-jerk returned.

I have seen a case which resembled this quite closely, and inasmuch as paralysis of all the ocular muscles appears to be a rather rare affection, the case may be worthy of mention here.

Observation XVII.—A boy, aged thirteen, after an attack of diphtheria developed paralysis of the soft palate. One week after the paralysis of the palate he noticed a disturbance of vision, which proved on examination to be due to a total paralysis of all the muscles of the eyeballs. The pupil reflex to light was preserved; but as he could not converge the eyes there was no reaction in accommodation. This paralysis of the eyeballs came on within twenty-four hours, and at the same time he developed a very marked degree of ataxia. He swayed in standing with eyes closed, and his gait was exactly like that of a well-marked case of tabes. The motion of the hands was also disturbed, and all the tests demonstrated an extreme degree of inco-ordination. The knee-jerks were lost; the skin reflexes were present. In addition to the ataxia there was actual weakness of the muscles, which was more evident in the arms and hands than in the lower extremities. He had formication in the legs, but not in the hands, and there were no lightning pains. He had great difficulty in swallowing solids as well as liquids, which seemed to point to some involvement of the muscles of deglutition as well as of the soft palate. This condition

remained stationary for about three weeks, and then all the symptoms began to pass off gradually. His recovery was not complete until six months after the onset.

The prognosis in cases of diphtheritic paralysis is usually very good, the fatal cases here cited being rarities. The treatment consists in general tonic medicines, and the application of electricity to the limbs in the same manner as in other cases of neuritis.

(*b*) Neuritis following variola is a rare complication, and the following case is the only one on record in which an autopsy proved the seat of the lesion.

Observation XVIII.—A young man had varioloid in November, 1881, and while convalescing, six weeks later, began to suffer from severe pains in his four extremities, especially in the joints of his arms, which were diagnosticated as rheumatic, although there was no fever. Soon after there followed a true paresis, with progressive atrophy of the muscles of forearms and legs. The muscles at the same time became very tender to touch or pressure. The tendon reflexes were much diminished. Reaction of degeneration developed in all the paretic muscles. The pains in the joints and limbs continued, but were less severe than at the outset. The sensibility of the skin was about normal. The nerve-trunks were tender to pressure. Profuse, offensive perspiration in all four extremities was a distressing symptom. There was no tendency to bed-sores, but an extensive pemphigus developed in the legs, and then the pains became more severe. The patient died in July, 1882, of pneumonia.

Autopsy showed the brain œdematous, and the cord in a state of hypostatic congestion. The pathological changes of importance were found in the nerves and muscles. The majority of the nerves of all the extremities were found in a state of degeneration and atrophy. There was marked degenerative atrophy and fatty degeneration of the muscles.[1]

(*c*) It is still somewhat a matter of conjecture whether cases of paralysis following typhoid, typhus, and malarial fevers are due to an affection of the peripheral nerves or of the spinal cord. The researches of Pitres and Vaillard[2] have shown that extensive degeneration of peripheral nerves is to be found in the bodies of patients who have died of typhoid fever, and they have also demonstrated that these fevers are often followed by local neuritis as a sequel. Cases of multiple neuritis with autopsies have not as yet been reported after typhoid or typhus; but Buzzard has recently recorded[3] two cases, following malarial fever, in which all the symptoms pointed to an affection of the peripheral nerves. In this country Gibney has described several cases of paralysis of the extremities, of sudden onset, rapid course, and prompt recovery under large doses of quinine, which he considered malarial. Probably the following case, which was kindly sent to me by Dr. L. E. Holt, was of this nature:

Observation XIX.—Peter S——, aged ten, a healthy boy, was suddenly seized with a chill and fever, and with pains of a severe kind in both legs, associated with weakness so that he could hardly stand. The pain was referred to the sciatic nerves, and was accompanied by numbness and tingling of the feet and legs. There was marked tenderness both in the course of the sciatics and in the muscles of the thigh and leg. There was loss of tendon reflexes, preservation of skin reflexes, and marked paresis in all the muscles of the legs, so that he required help in walking. There was no ataxia, and no incontinence of urine. The symptoms lasted about twenty-four hours, and then decreased in severity gradually during the following day, but recurred on the third, and, after a remission, on the fifth day, with lessened severity. The periodicity of the affection and the rapid cure under quinine left no doubt as to its malarial nature. During the third day, at the time when I saw him, there was redness along the course of the sciatics, and in the region of the right median nerve, and extreme tenderness along these nerve-trunks, in addition to the symptoms mentioned. The electric condition was, unfortunately, not tested; but in Westphal's case faradic contractility was totally abolished during the attack.[1] In this case the active manifestation of the malarial poisoning was by a general neuritis. In Buzzard's cases the malarial attacks preceded the nervous affection. The tenderness in muscles and nerves left no doubt regarding the peripheral nature of the disease.

And here I may suggest that it is possible that many minor nervous affections of transient nature and of malarial origin, if more carefully examined, will be found to be due to some abnormal condition in the peripheral nerves. I allude not only to neuralgiæ, but also to visceral neuroses, whose clinical features have been so graphically described by Dr. Clifford Allbutt,[2] and to numb fingers and toes, and to hyperæsthetic and painful areas on the surface, and that host of symptoms of a local character so often carelessly ticketed neurasthenia and dismissed from consideration as soon as named. There is much in the study of the phenomena of neuritis to enforce this suggestion which cannot be developed here.

(*d*) We come, lastly, to those cases of multiple neuritis which occur in tubercular patients, or in those who have had syphilis. If a review of the cases of multiple neuritis already cited be made, it will be found that quite a number of the patients died of phthisis. This was true of the cases of Joffroy, Eisenlohr, Strümpell, Webber, and Müller. Oppenheim[3] has reported cases of multiple neuritis in tubercular patients which went on to recovery. The following case died:

Observation XX.—A young girl, who had had syphilis, and was suffering from phthisis, took a severe cold and began to have pains in the joints, weakness, and numbness of the lower extremities. The weakness of the legs increased rapidly, and was attended by rapid diffuse atrophy. The same symptoms soon developed in the arms. Four weeks after the onset partial RD was present in all the extremities, and total paralysis of the legs and nearly complete paralysis of the arms were present. In the course of the disease, which lasted five months, there was little pain, but great tenderness of the muscles and hyperæsthesia of the skin. The sensation was diminished in feet and hands, but this was slight in comparison with the motor symptoms. The paralysis finally attacked the trunk muscles and the diaphragm, while the beginning of rapid heart action was thought to indicate paralysis of the pneumogastric nerve. Great prostration, delirium, incontinence, bed-sores, and œdema of extremities, with fever, preceded death.

Autopsy: High degree of degeneration of the peripheral nerves, including the phrenic and pneumogastric, was found, with a moderate degree of atrophy of the muscles. Cord normal, anterior motor roots normal. The changes in the nerves were similar to those after section, viz., a simple degeneration of the fibres with some increase in the connective tissue, but there were no evidences of changes in the vessel-walls, no infiltration with cells. The nerves contained very few normal fibres. The myelin sheaths were found in all stages of destruction, down to an entire absence of contents of the sheath of Schwann. Throughout the fibres fatty and granular masses were found. The sheath of Schwann did not, however, show an increase of nuclei.[4]

Such a case as this would have been ascribed, a few years ago, to a tubercular spinal meningitis, as would many of the other cases already alluded to. It is not my purpose to dispute in any way the fact that many cases of paralysis occurring in the course of phthisis are due to lesions of the central nervous system and its membranes; but I desire to emphasize the fact that a multiple neuritis may produce paralysis in tubercular individuals,

[1] P. Grocco, Milano, 1885; Centralbl. f. Med. Wissen., 1885, p. 693.

and the importance of appreciating this possibility cannot be too strongly urged, since the treatment, as well as the prognosis, will differ widely according to the diagnosis made. It has been known for some time that local neuritis may complicate phthisis, and the researches of Pitres and Vaillard have recently confirmed this fact. But the complication of multiple neuritis is one not mentioned in the text-books, and yet is one which is by no means rare. It seems not unlikely that some of the nervous symptoms in consumption, formerly considered functional, may be traced to this affection.

Although syphilis has been described as a cause of neuritis, I cannot find that the lesion in the few cases examined has had the peculiar characteristics of syphilitic lesions elsewhere in the body, and therefore it seems to me doubtful whether we are justified in describing a syphilitic multiple neuritis. Further facts are needed to establish its existence.

(*e*) It only remains to consider briefly the epidemic form of multiple neuritis, and our study of the infectious cases will be complete.

In 1882 Professor Scheube, of Tokio, Japan, called the attention of European physicians to the existence of a peculiar affection prevailing among the Japanese.[1] It was called kakke; from two Chinese words, *kiaku*, meaning legs, and *ke*, meaning disease. It had been known among the Chinese for centuries, being mentioned by name in Chinese medical books written two hundred years before the birth of Christ, and fully discussed by an eminent author in 640 A.D. It ceased, however, to prevail in China about two hundred years ago, and its ravages are now confined, according to Scheube, to Japan. There its importance is considerable, since it is so prevalent that in 1877 fourteen per cent., and in 1878 thirty-eight per cent., of the men serving in the army suffered from it. It is considered a miasmatic infectious disease by Scheube, although an eminent Japanese authority considers it due in some way to the diet of rice. That diet has something to do with its occurrence is proven by the fact, communicated to me by Dr. Wallace Taylor, that since wheat has been substituted for rice in the diet of some of the barracks and prisons in Japan the disease has been less common. It occurs in epidemics, but is always endemic in Japan. It does not attack Europeans. It affects females rarely, only nine per cent. of the cases being in women; and it is the youth of the land, between the ages of sixteen and twenty-five, who are attacked. Exposure to damp and cold in crowded dwellings, such as barracks, increases the liability to the affection. The majority of the cases occur during the hot months, but some are always under observation. This disease is not, however, confined to Japan. It has been observed for many years in the islands of the Pacific Ocean, in India, Ceylon, on the west coast of the Red Sea, in Borneo and New Guinea, in Brazil and Cuba, and its prevalence in the Dutch possessions in the China Sea has made it familiar to physicians from Holland who have visited these colonies. It is there known under the name of beriberi. It is endemic in these regions, but occasionally occurs as an epidemic. An interesting account of such an epidemic, occurring in 1882–83 in Manila, the chief city of one of the Philippine Islands, has been given by Dr. Koeniger.[2] It appears that in the fall of 1882 an epidemic of cholera occurred in Manila, of such severity that twenty thousand persons, in a population of four hundred thousand, were affected. As a precaution against this disease the native population lived for several months almost exclusively upon rice, refusing to eat fruit or fish, which are their other chief articles of diet. As the epidemic was subsiding a terrible cyclone devastated the city, destroying the light wooden houses, and leaving sixty thousand families homeless; and these poor people were exposed for several weeks to the inclemency of the weather, which at this time of the year is rainy. A few days after the cyclone the epidemic of beriberi began, and as the disease had never before appeared in Manila the unknown affection excited great alarm. This was increased by its fearful mortality, sixty per cent. of the early cases proving fatal. Europeans were exempt, with two exceptions, and the Chinese population did not suffer greatly, but among the natives the epidemic was wide-spread. Thus, in one suburb of Manila, of twenty-five thousand inhabitants three hundred died in the course of eight weeks. Men and women were equally affected, and persons of all ages, except young children were attacked. The disease terminated fatally in from ten days to five weeks after its onset; but as time went on the proportion of recoveries increased, and by the end of March, 1883, it had almost disappeared. The months from October to March are the dry, cool season in the Philippine Islands, although the climate is tropical. Exposure to heat could hardly be considered a cause of this epidemic, but whether the exposure to cold and damp, or the diet of rice, or the transportation of some infectious agent by the cyclone was the cause, gave rise to much discussion, and could not be determined.

Sporadic cases of beriberi, or kakke, occasionally appear in our hospitals, usually in the persons of Chinese or Malay sailors, or in the persons of travellers from tropical climates who have been exposed to the infection in the place from which they came. Three such cases have recently been reported by Dr. Seguin, of this city,[1] in patients who came from the West Indies, and a case observed in Bellevue Hospital, by Dr. J. West Roosevelt, was discussed in the Academy of Medicine recently. In 1881 a Brazilian naval vessel entered San Francisco with a large number of the crew affected by the disease. They were sent to the United States Marine Hospital, and attended by Dr. Hebersmith, who gave an interesting account of the circumstances leading to the development of the disease in the United States Marine Hospital Report.[2] From this report the following map is taken, which demonstrates the localities in which beriberi is endemic.

Only last year a commission was appointed by the Dutch Government to investigate the subject of its nature, and the recently published report contains the following statements:[3] The disease is caused by a micro-organism resembling the bacillus of splenic fever, though somewhat smaller, which colors with fuchsin and gentian-violet, and can be seen with a power of 560°. These bacilli are found in the blood, lungs, heart, brain, cord, and nerves of the patients, and can be cultivated outside of the body. The germs infect wooden dwellings chiefly. They may be conveyed by articles of clothing, and probably enter the body by the lungs. Direct contagion has not been observed. A potent predisposing cause to their reception in the body and to the development of the disease is lack of nutrition, consequent upon exposure to damp and to cold, and upon insufficient or bad food. It must, however, be added that a most thorough examination in Dr. Roosevelt's case, by Dr. Prudden, failed to reveal the presence of such bacilli.

In the light of these recent investigations a new view is taken of an epidemic of a peculiar kind which occurred in France in 1828. Buzzard has found an account of this, prepared by Graves, in which the symptoms are so fully detailed as to leave no doubt that it was an epidemic of multiple neuritis.[4]

The cases of beriberi are divided into two general classes, according to their severity.

There are, first, slight cases, in which the onset is gradual, being usually preceded by a little fever, coryza, and conjunctivitis, which cease when the actual symptoms commence. The patient first notices a weak and heavy feeling in his legs, and finds that he tires so easily that

[1] Deut. Arch. f. Klin. Med., xxxi. and xxxii. [2] Ibid., xxxiv.

[4] Buzzard: On Paralysis from Peripheral Neuritis, p. 37.

he cannot walk as much as usual. The tired feeling is soon associated with numbness and pain in the legs, and with a slight œdematous swelling. Then, if not before, palpitation of the heart, oppression and weight in the epigastrium, loss of appetite, and general malaise are felt, and the patient finds it necessary to apply for treatment. An examination then shows some diminution of power in the feet and legs, and also in the hands, with loss of tendon reflexes, and much tenderness in the muscles, which show a diminished electric excitability. There is never any ataxia, though the patient sways when his eyes are closed. There is discovered a slight degree of anæsthesia, of irregular distribution, chiefly in the legs and in the radial-nerve region on the forearms. Though the patients look pale, it is usually impossible to find anæmia by examination of the blood.[1] The circulation in the extremities is sluggish. The heart is irregular and rather rapid, and the œdema of the extremities indicates a failure of its power. Dr. Wallace Taylor[1] finds that a sphygmographic tracing is characterized by a sudden high upstroke in ventricular systole, by a precipitous descent from the apex of the percussion-wave, and by dicrotism. Beyond this point these cases, which make up the majority, do not advance. They usually recover in a few days, or at most a month; although a few become chronic and require several months before the cure is complete.

There are, secondly, severe cases. These may present three different types. There is the atrophic or dry type, in which, after an onset similar in nature to that in the slight cases, but much more rapid, the weakness develops into a true paralysis, associated with marked wasting of the muscles and reaction of degeneration, with great diminution of galvanic excitability. Within a week the patient has to go to bed, and then the paralysis soon spreads from the legs to the arms, and may involve the trunk and even the face. The entire muscular system wastes away till the patient is a mere skeleton. In addition to the motor symptoms there is great sensory disturbance. The suffering from pain, paræsthesiæ, and general muscular tenderness is extreme, and the patient lies totally helpless and unable to tolerate the lightest touch. The skin may be glossy. There is usually some anæsthesia, but it is never complete, although it may involve the entire body. The temperature sense is seldom affected. Pain may be delayed in transmission. There are no gastric symptoms, and no œdema. Some cases prove fatal from general exhaustion, or intercurrent disease, but the majority recover after a convalescence which lasts a year or more, during which the muscular system is rebuilt.

There is, secondly, the hydropic or wet type. In these, heart-failure appears early, and is associated with a marked decrease of arterial tension and much œdema of the entire body, effusion into the cavities being added to that beneath the integument. The swelling of the edematous parts conceals the atrophy which is going on in the muscles, but this is indicated by the paralysis, which is as severe as in the preceding form, and it becomes evident during recovery when the œdema has subsided.

There is, thirdly, the acute pernicious type. In this all the symptoms of the two former types appear in rapid succession, and, in addition, gastro-intestinal symptoms and a suppression of urine combine to make the condition an alarming one. Effusions into the pleura and pericardium appear early. The pulse becomes small and irregular, and cyanosis indicates the heart-failure which precedes death.

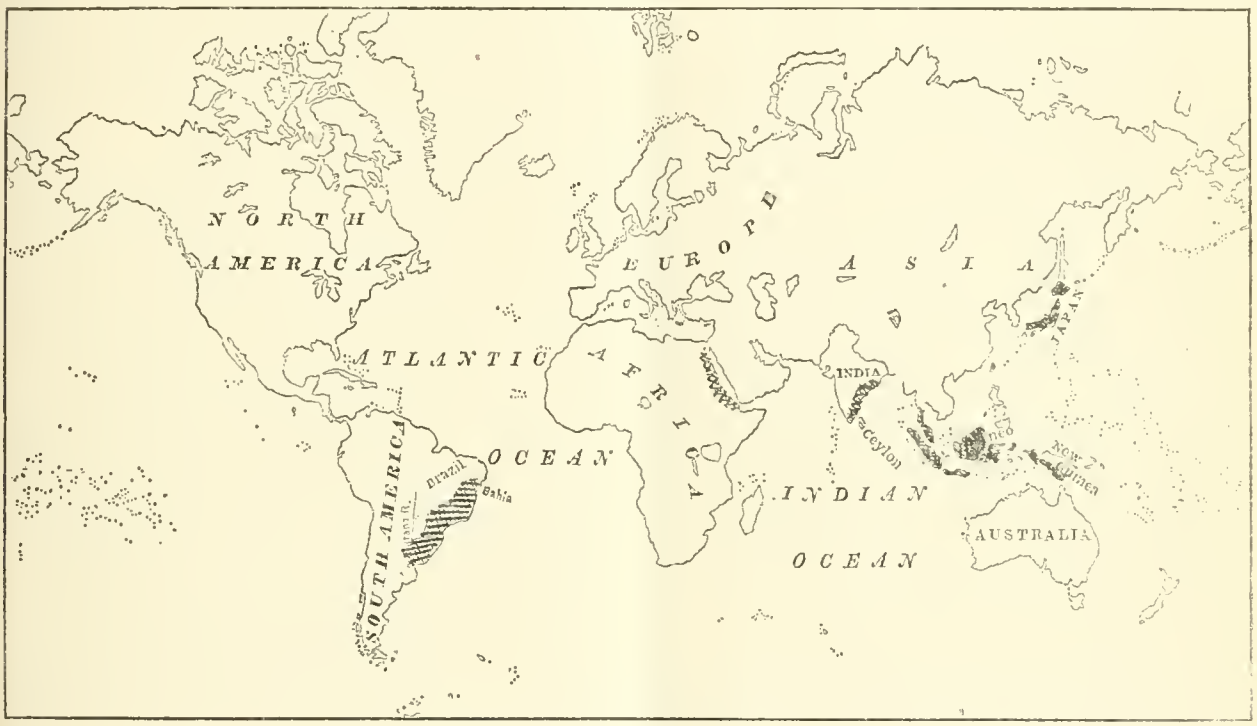

FIG. 6.—Sketch Map indicating the Geographical Distribution of Beriberi. (From United States Marine Hospital Report, 1881.)

In this form the disease may run its course in two weeks to a fatal termination. This was the form which chiefly prevailed in Manila, the cases of the atrophic form being the ones which recovered.

The severity differs much in different epidemics, the mortality varying from two per cent. in Japan to sixty per cent. in Manila. It is usually not above three per cent. In all the forms there is some danger of a sudden heart-failure, and this is usually the cause of death.

The morbid anatomy of the disease is, primarily, a multiple peripheral neuritis, with, secondarily, numerous organic changes in various organs, none of which, however, are essential to the disease.[1]

While we cannot join in the wish expressed by an enthusiastic German author, that the disease may soon become a familiar one to those outside of Japan, we cannot pass it by without a brief reference, especially as it resembles in so many of its features, as well as in its pathological basis, the condition which has occupied our attention at present. And it may not be unprofitable to obtain a clinical picture which differs somewhat from

[1] Scheube: Virch. Archiv, Bd. 95, s. 146.

that already viewed, in connection with the forms more familiar to us, in order to detect sporadic cases of the disease, if such should appear among us. As to its treatment, it may be mentioned that quinine failed to influence its course, and that heart-stimulants to combat the dangerous complications, hypnotics to counteract the pain and insomnia, and general tonic treatment have proved of the greatest service. Change of climate often is attended by recovery. In the stage of recovery electricity and massage have been employed with advantage.

III.—In a considerable number of cases of multiple neuritis no cause of the disease could be definitely ascertained. Great fatigue by walking, or by hard labor, and exposure to dampness and cold are assigned as causes in some of these cases, and may have acted as etiological factors. In others the disease seems to have developed spontaneously.

The following cases are cited as belonging to this class:

Observation XXI.—A perfectly healthy man, aged thirty-four, after a long and fatiguing walk was suddenly attacked with weakness of the legs, pain, and formication, which increased so rapidly that in two days he could not walk, and in eight days was totally paralyzed—legs, trunk, arms, face, and pneumogastric nerve being all involved. The paralysis was attended by severe pains, tenderness along the nerves, profuse perspiration, fever, and jaundice. Further, a diminution of sensibility, a loss of tendon reflexes, a loss of muscular sense, a rapid atrophy, with reaction of degeneration, were observed; and trophic disturbances, consisting of an abnormal growth of hair and pigmentation of the skin, as well as vasomotor disturbances in the form of œdema, appeared. There were no fibrillary muscular contractions, no increase of mechanical excitability, and no incontinence of urine or fæces. During the following four months a gradual improvement took place, which went on to final recovery a year and a half after the onset. The only anomaly at that time was an absence of contractility of the muscles to the electro-current, when excited through the nerve.[1]

Observation XXII.—A female, aged forty-two, previously in good health, was attacked, on October 1st, with pain in the back and in all four extremities, attended by great weakness, which increased so rapidly that on October 13th there was found to be an almost total paralysis of both legs, of the trunk, and of certain muscles of the arms. The pains were accompanied by a feeling of formication and a painful sensation of tingling. When first seen by Dr. Guttmann there was total paraplegia, slight movements in fingers and toes being the only motion possible; the muscles were all relaxed and flabby, were much atrophied, were tender to pressure, and a few of the smaller muscles showed slight diminution of faradic excitability. There was no disturbance of sensation. The tendon reflexes were abolished. The sphincters were not involved. The temperature was normal, but the pulse was unduly rapid. There were no bulbar symptoms. Under large doses of iodide of potassium and the application of faradism, the patient recovered completely in the course of three months.[2]

In some of the cases of this form the early pains were located in the joints, and led to the diagnosis of rheumatism. The fact is merely mentioned to call attention to the possibility of mistake. A careful examination will never fail to correct it.

Symptoms.—Turning now to the consideration of the individual symptoms of multiple neuritis, and their course, we are at once impressed by their number and variety.

The *sensory symptoms* are the earliest to appear and the last to pass away. In the majority of the cases on record, from whatever cause, numbness, tingling, or formication usher in the disease. These forms of paræsthesiæ begin in the feet and hands, and extend to the knees and elbows. They may be associated with burning, stretching, boring, or tearing sensations, which distress the patient, especially during the onset. But all such sensations usually subside as the affection reaches its height. Their recurrence, as the case goes on, may be regarded as a favorable symptom, however annoying, for they frequently precede recovery, and are among the last evidences of the disease to disappear. Pain is usually present as well as paræsthesiæ. It may occasionally be sharp in character; but is usually moderate and not continuous. At times it may be lancinating, and so severe as to necessitate the use of morphia. But it is rarely as distressing as in cases of locomotor ataxia. Tenderness in the nerves and muscles is a constant symptom. It may be so marked that the limbs cannot be moved or handled, and thus it may interfere with the application of electricity and massage. When the tenderness and pain are referred to the joints, as not infrequently occurs in the early stage of the disease, the case may be mistaken for one of acute articular rheumatism, and if the joints are swollen or the limbs edematous the difficulty of diagnosis is greatly increased.

In addition to these subjective feelings some demonstrable disturbance of the various sensations is usually present. Hyperæsthesia to touch, and also to electricity, is not infrequently observed during the first few weeks. It is usually followed by some anæsthesia, although this rarely becomes complete. In some cases the loss of tactile sense is quite evident from the outset, either limited to the cutaneous distribution of some special nerve, in which case oddly shaped areas of insensibility will be found, or, as is most often the case, about uniformly distributed over the distal parts of the extremities. When the anæsthesia is at its height the patient has difficulty in locating a touch upon the limb, even though he feels it. The transmission of pain and temperature-sensations is always delayed, but the impressions are usually felt quite acutely. The sense of pressure has been tested in only a few cases, and in those it was decidedly impaired. The muscular sense escapes any affection in some cases, but in others is the most profoundly disturbed of all the senses. When it is involved, the inco-ordination and ataxia are well-marked symptoms, and, as already stated, some of the cases have been mistaken for locomotor ataxia, because of the predominance of the disturbance of muscular sense.

These sensory symptoms are usually limited to the forearms and hands, and to the legs and feet. In a few cases they have involved the entire extremities, and even the trunk; and one case of facial tingling, with anæsthesia, has been recorded.[1] The skin reflexes are usually preserved.

The special senses are rarely affected in multiple neuritis. It is true that optic neuritis has occurred in a few cases, and in two cases hearing as well as sight has been affected. These cases prove that no nerve can be said to be exempt from implication in this disease, but the liability to affection seems to be slight in the case of the nerves of special sense.

The *motor symptoms* are as marked and as important as the sensory. Paralysis, beginning as simple weakness, with a feeling of fatigue on any exertion, gradually increases in severity until at the height of the disease it becomes complete. It usually comes on rapidly, so that within two weeks the patient is helpless; but it may be less sudden, and not deprive him of the power of walking and of using his hands for two or three months. In a few cases a very acute onset is recorded, all the symptoms developing within three or four days. The distribution of the paralysis is not uniform at the outset. It may develop in the muscles supplied by a single nerve, and advance to others; it may begin in all the muscles of the legs, and then involve those of the forearms; it may

[1] R. H. Pierson: Ueber Polyneuritis Acuta, Volkmann's Klin. Sam., 1883, No. 229.

[2] Guttmann: Deut. Med. Wochenschr., 1884, No. 19.

[1] Lowenfeld: Neuro. Centralbl., 1885, No. 7.

commence in all four extremities at once. It is always more severe in the muscles which move the joints of the feet and hands, and the ankles and wrists. It rarely invades those which move the knees and elbows. When the disease is fully developed, all the muscles below the knees and elbows are much weakened or totally paralyzed. In a few cases those of the thighs and arms are involved also, and occasionally the muscles of the trunk and those of respiration become affected and the patient dies. When such a paralysis makes rapid progress and involves all the body, the case resembles Laudry's paralysis. But in multiple neuritis, as has been already stated, the disease does not creep up from legs to thighs, and then to trunk and arms, as in Laudry's paralysis. It spreads from feet to hands, from legs to forearms, and the trunk is invaded only at the end, and in Laudry's paralysis sensory symptoms are wanting. In some cases of multiple neuritis the cranial nerves become involved; those of the eye and of the face being most liable to invasion. It is only in fatal cases that the action of deglutition has been affected; and when the pneumogastric is invaded, and the heart becomes rapid and irregular, the prognosis is always grave. Spasms rarely occur.

The paralyzed muscles are relaxed, flabby, and atrophied; they may or may not lose their mechanical irritability, but their normal tone is always lost, and hence the so-called tendon reflexes are abolished.[1] To the electric current their excitability is very rapidly and markedly changed; but the conditions which have been observed are quite various. Sometimes there is a simple diminution of excitability, and then a very strong faradic or galvanic current is needed to produce contractions. Frequently all faradic excitability is lost, and then the muscles react to a galvanic current only. In this condition it may require a very strong galvanic current to produce contraction, and this fact is quite pathognomonic of neuritis. For an anterior polio-myelitis, where the muscles respond to galvanism only, it does not require a strong current to cause a motion until some months after the invasion. The action of the different poles is not uniform. In many cases the contraction of the muscle when stimulated with the positive pole is greater than when stimulated with the negative pole, and the contractions may be sluggish. Then the reaction of degeneration is present. But in some cases the normal condition is found, and the negative pole produces stronger contractions than the positive pole. If the muscles that are not paralyzed be tested, the same electrical changes may often be discovered in them. A loss of faradic irritability and a marked decrease in the galvanic irritability of the muscle and nerve are, therefore, important symptoms of multiple neuritis. And as the disease goes on to recovery a gradual increase in the galvanic irritability occurs, a fact which is often of much aid in prognosis if careful measurements of the strength of current used be made by the galvanometer. I am accustomed to record such measurements upon charts, and thus to obtain an electric curve for each muscle which is paralyzed.[2] These curves enable one to judge of the progress of the case quite accurately, and when the line is advancing steadily toward the normal point, after a great deflection or after a stationary level, the prognosis is very favorable.

As a result and accompaniment of the paralysis *abnormal positions* are assumed by the limbs. The dropped wrist and dropped foot are quite characteristic of multiple neuritis. But other deformities may be present. In a few cases there have been extreme contractures of all the extremities in flexed position. And not infrequently the appearance of the claw-shaped hand, and some one of the various forms of talipes, indicates a serious shortening of one set of muscles, and corresponding weakness of its opponents. These deformities usually subside as the power returns, or if they do not they can be corrected by proper manipulation and by apparatus. In a few cases it has been necessary to resort to tenotomy, but a permanent deformity has not been recorded.

The *vaso-motor and trophic symptoms* are less constant than those already described. In some cases marked œdema has been an early and a permanent symptom. This may develop in the feet and hands, or may appear about the joints. It usually is temporary. The circulation is not impaired any more than is customary in a limb whose muscles are inactive, and coldness and cyanosis are rarely sufficient to attract attention. Sometimes profuse perspiration is a noticeable symptom, being limited to the paralyzed parts. It may be offensive, and by its evaporation always causes a complaint of coldness. In other cases glossy skin makes its appearance early, and remains until regeneration of the nerves begins. Its disappearance in one of my own cases was the first sign of recovery in the lower extremities. Other forms of trophic disturbance are rarely met with in multiple neuritis. And this is quite remarkable in view of the fact that it has been the tendency of late to refer such trophic affections as ulcerations, bed-sores, gangrene, pemphigus, and various eruptions to lesions of the nerves.[1] It is true that inflammations of the joints, resembling those appearing in acute rheumatism, sometimes occur at the onset of neuritis; but as they disappear quickly, while other symptoms remain, it is improbable that they are to be traced to the changes in the nerves. They may be due to the infectious agent, or to the same obscure cause which sets up the neuritis, or they may be evidence of an attack of acute articular rheumatism, which is in turn followed by neuritis; but they cannot be described as trophic symptoms of the disease, otherwise they would be more constant in their occurrence and more permanent in their duration.

A negative symptom of some importance is the absence of any interference with the automatic acts controlled by the sphincters.

One word about the onset. Occasionally it is sudden and accompanied by a marked febrile movement, with chill, and temperature of 103° to 104.5° F. The fever may persist for several days, but usually subsides spontaneously and does not recur. In a few cases there has been a constant elevation of temperature from one-half a degree to one and a half degree above the normal; and an increase in the rapidity of the pulse throughout the disease has been noticed. A pulse of ninety need give no alarm, but if it runs up to one hundred and forty, and becomes irregular, there is reason to believe that the disease has attacked the vagus nerve, and then the prognosis becomes serious, though not by any means hopeless.

The duration of the disease varies considerably in different cases. An average of twenty-five cases gives seven months as the probable time required for complete recovery. But in these cases the duration varied from two months, in the most favorable, to sixteen months, in the most refractory.

The disease is more common in males than in females, excepting the form produced by alcoholism. Of 47 non-alcoholic cases, 33 were males.

All ages are liable to be affected, but in the records of multiple neuritis, excepting the form produced by diphtheritic poison, the cases recorded do not include any children.

That children may be affected is, however, not at all improbable. Dr. H. D. Chapin, of this city, has described four[2] cases of atrophic paralysis in children, in which the presence of sensory symptoms, pain and mus-

[1] A few exceptions to this rule are found in two cases recorded by Strümpell and Mobius, Munchener Wochenschrift, 1886, No. 34, and in Brit. Med. Jour., January 1, 1887.

[1] Raynaud's disease has recently been ascribed to neuritis. See J. Wigleworth, Brit. Med. Jour., January 8, 1887.

[2] Painful Paralysis in Children, New York Medical Record, January 15, 1887.

cular tenderness, and the steady progress toward recovery pointed to the existence of multiple neuritis. The cases were such as are usually called infantile paralysis, but there were points of difference (viz., the existence of sensory symptoms) which removed them from this category. Leyden called attention to the possibility of mistaking neuritis for poliomyelitis in his first article upon the disease, but he referred to adult cases rather than to children's cases. And if the surmise of Chapin should be substantiated by autopsy, it might be necessary to conclude that in children, as well as in adults, the majority of cases of supposed poliomyelitis which recover are cases of multiple neuritis.

In adults, out of 50 cases 6 were between the ages of 18 and 20; 8 between 20 and 30; 20 between 30 and 40; 8 between 40 and 50; 5 between 50 and 60 and 3 over 60 years of age.

Diagnosis.—While the individual symptoms occurring in the course of multiple neuritis are not different in character from those found in spinal-cord diseases, the diagnosis can usually be reached with very little difficulty when their combination, the causation, and the course of the case under examination are considered. The varying combination of the symptoms possible has been manifest during their description, and it is not my intention to review them again. There are, however, three combinations which resemble very closely, respectively, anterior poliomyelitis, locomotor ataxia, and diffuse myelitis, and to these attention must be directed.

Atrophic paralysis, with reaction of degeneration and loss of reflex is common to anterior poliomyelitis and some cases of multiple neuritis. In the latter a more gradual onset, preceded and attended by numbness and pain, tenderness in the course of the nerves, tenderness in the muscles, and the persistence of sensory symptoms after the invasion, will remove all doubt regarding the diagnosis. When these symptoms are not clearly marked, the distribution of the paralysis in symmetrically situated muscles, especially if these muscles are supplied by single nerves, and the further extension to muscles in other nerve domains, rather than the affection simultaneously of muscles which are grouped physiologically (*i.e.*, act together to perform one function), will point to neuritis. In neuritis the paralysis advances more or less gradually, while in acute poliomyelitis there is, after the onset a subsidence of the paralysis in some of the muscles first involved. And lastly, as the case goes on, a gradual complete recovery will be far more frequent if it was originally a case of multiple neuritis.

Ataxia, loss of knee-jerk, pain, and sensory disturbances, including a loss of muscular sense, Romberg's symptom, and optic neuritis are common to locomotor ataxia and multiple neuritis. In the latter the relatively rapid onset of the ataxia, which follows closely upon the sensory symptoms; the prominence of numbness and anæsthesia, rather than of lightning pains; the extreme degree of the anæsthesia and analgesia; the tenderness of muscles and nerves; the usual occurrence of some degree of actual paresis with atrophy and RD; and the absence of bladder and sexual symptoms will point inevitably to the diagnosis. Furthermore, the ataxic form of neuritis only occurs after poisoning with alcohol or arsenic, or as a sequel of diphtheria, and the establishing of the causation will aid the diagnosis. Here, again, the course of the case toward recovery, with return of the knee-jerk, will decide in favor of neuritis, if the diagnosis has not been reached in an early stage.

There are very few symptoms of diffuse myelitis which are not found in cases of neuritis. But cases of diffuse myelitis of the type of Duchenne—paralysie générale spinale subaigüe ascendante—are very rare, and indeed by Leyden it has been affirmed that all such cases are multiple neuritis. Other authorities dispute this assertion and leave us to establish points of difference. These are as follows: In neuritis affections of the functions of micturition and defecation do not occur. Girdle sensation is very rarely mentioned as a symptom; bed-sores and cystitis have not been observed. The advance of the paralysis is rarely from the legs to the thighs and trunk, and then to the arms; it is usually from the legs to the forearms, the trunk and thighs escaping, and, as a rule, the distal portions only of the extremities are paralyzed. If the muscles of the abdomen and respiration are involved, it is only in rapidly fatal cases. In neuritis there is usually some ataxia, and loss of muscular sense is quite evident; while in some, at least, of the cases of myelitis of Duchenne, there were no sensory symptoms at all. Finally, the tenderness of muscles and nerves, and the absence of tenderness to pressure or to heat in the spine, would decide in favor of neuritis. The diagnosis from meningitis of the cord, from tumors or hemorrhages into the cord, or from general paralysis of the insane, would rarely present any difficulty to one who was familiar with the symptoms in those affections, and who knew the prominent features of multiple neuritis.

No small difficulty may be encountered, however, in settling the question whether in a given case we have to deal with multiple neuritis alone, or with multiple neuritis which is complicated by myelitis. The importance of the question is evident, since the prognosis in the two conditions is very different; and the number of autopsies on record in which this complication has been demonstrated, though few, is sufficient to make a decision of the question necessary.[1] The following points may enable a determination of the question to be reached: (1) As long as a case is increasing in severity, or in the extent of the symptoms, no one can determine the extent of the lesion. It is only when its course has become stationary that the question of exact limitation will arise. Many cases remain practically without improvement for three or four months, and then gradually recover. A stationary condition alone does not, therefore, excite fear of a complication. But neuritis tends spontaneously to recover, the process of regeneration beginning soon after the degeneration has ceased. If, therefore, there appears to be no improvement of the condition after the fourth month, the probability is either that the cause of the disease has not been removed, or that a myelitis has developed and prevents recovery. (2) The course of a case of neuritis is quite characteristic, the symptoms reaching their maximum in a short time, and then subsiding. If, after a stationary period, further symptoms develop, we must believe either that the cause of the disease is renewed (*e.g.*, the use of alcohol) or that myelitis has begun. The symptoms of such a myelitis will be an increasing weakness and more rapid and progressive atrophy of the muscles; a gradually decreasing degree of galvanic excitability in the paralyzed muscles; a loss of pain and temperature senses, which, as a rule, are not affected in neuritis; a decrease in the paræsthesiæ, and an increase in the degree of anæsthesia; the development of loss of control over the sphincters; the occurrence of bed-sores, furuncles, eruptions of a bullous nature; and the beginning of cystitis. (3) On the other hand, if the symptoms are gradually improving; if the power gradually returns; if the anæsthesia decreases, and is succeeded by paræsthesiæ, however disagreeable to the patient; if the galvanic excitability becomes gradually more acute in the muscles, so that the electric curve approaches the normal line; if the faradic contractility returns in the muscles; if the tenderness of muscles and nerves decreases; and if the glossy appearance of the skin disappears, it may be stated that no complication of myelitis has occurred, and that recovery, though possibly prolonged, will at length result.

Another question of diagnosis must also be considered. It is found that in no small number of cases of locomotor ataxia multiple neuritis develops as a complication. How can we determine when this complication exists? The symptoms of the two diseases may be so nearly iden-

[1] Oppenheim, Zeit. klin. Med., xi., 232; Leyden, Charité Annalen, 1878; Duménil, Gaz. Heb., 1861.

tical that difficulty arises in distinguishing them. When they coincide it is equally difficult to determine to which disease any given symptom belongs. Pitres and Vaillard,[1] who have considered this subject most carefully, affirm that there is no constant relation between the severity of the central and peripheral lesions when they coincide. But there are certain symptoms which develop in some cases of tabes, but not constantly, which may be looked upon as accidental, and thus traced to neuritis. Such are the appearance of plaques of anæsthesia and analgesia of limited area, muscular weakness or paralysis of limited extent, trophic disturbances in the skin (*e.g.*, perforating ulcer), nails, joints (*e.g.*, Charcot's disease), bones (*e.g.*, spontaneous fractures), and teeth (*e.g.*, spontaneous falling out), and possibly the various crises referable to the viscera and larynx. In cases which competent observers have examined, peripheral neuritis has been found *post-mortem* in the nerves supplying the parts in which these symptoms appeared. It is, therefore, reasonable to conclude that in any case of locomotor ataxia in which these symptoms develop we have to deal with a posterior sclerosis which is complicated by a peripheral neuritis. And here again the distinction has a bearing upon the prognosis, for the symptoms of the accidental kind may pass off, while those due to the central lesion will remain. While these conclusions of the French authors are of importance, it must be noticed that their claim that trophic disturbances are due to a complicating neuritis is by no means substantiated by the history of cases of multiple neuritis, in which, as we have seen, trophic disturbances of the varieties mentioned do not often occur.

Prognosis.—The prognosis in multiple neuritis is good, provided the exciting cause can be removed. The only cases which form an exception to the rule are those whose constitutions are much impaired by excesses or by other diseases; those who have so far indulged in alcohol or are so completely soaked with arsenic or lead as to be unable to throw off the poison; and those in whom the disease begins with great suddenness, advances rapidly, and involves the phrenic and pneumogastric nerves. These cases either die of respiratory paralysis or of some complication. When a case has reached the stationary period the prognosis is generally favorable, and if the encouraging signs of recovery already mentioned begin to appear a cure may be promised. The possibility of the complication of myelitis must not, however, be overlooked, and if it occurs the prognosis becomes at once unfavorable. Even in serious cases of alcoholism, with gastro-intestinal and cerebral symptoms, if the acute stage is safely passed and all alcohol be removed from the patient's diet, recovery from very extensive paralysis will occur. The cases of diphtheritic paralysis and ataxia usually recover without treatment. The cases occurring with syphilis and tuberculosis are not so uniformly favorable, although the former usually respond promptly to specific treatment, and even the latter may recover wholly. In epidemics, the percentage of mortality has been found to vary, but is usually low.

Treatment.—The treatment of multiple neuritis requires patience, but receives the reward of success. As we have already seen, the majority of the patients recover, and it is probable that, if the cause of the affection were removed and the patients placed in favorable circumstances, expectant treatment would alone be sufficient. It is, however, not advisable to let therapeutics play a passive part. The course of the disease can be altered and its duration much shortened by active interference. In the stage of invasion the free use of salicin, salicylic acid, or the salicylate of soda seems to have important results. These remedies cannot be said to act as promptly as in cases of acute articular rheumatism, but the consensus of opinion is that their effect in multiple neuritis is very marked. They should be given, as in acute rheumatic fever, in large doses until noticeable effects are obtained. They should be combined with the bromide of potash or soda, partly because these drugs counteract unfavorable symptoms produced by the salicin compounds, and partly because in the hyperæsthetic irritable condition attendant upon the invasion of the disease they are indicated. This condition may require stronger sedatives, and not infrequently morphine must be employed to give relief from the excruciating pains. The pains are often relieved by hot or cold applications to the limbs; but as the muscles are often exceedingly tender ordinary applications cannot be made. It is then advisable to use evaporating lotions, preferably those containing chloroform, which may be soaked into light cambric or gauze, and gently placed upon the limbs, which lie upon the softest pillows, or which may be more comfortable if the patient is put upon a water-bed. Applications of a five per cent. solution of carbolic acid have also been of use. If cool applications prove intolerable, heat may be employed. The limbs may be enveloped with cotton and covered with oil-silk, a light bandage keeping these in place; or they may be frequently bathed in hot water, and hot bottles placed against them, some soft substance intervening. One of my patients found great relief from the paræsthesia by cold douches, while another preferred the use of hot water. It is best to let the patient decide as long as the application has to be made for the relief of pain. Gentle friction with oil of cocoanut often affords comfort. In the chronic stage, as we shall see presently, heat is to be preferred to cold. Cases which are distinctly syphilitic, if such occur, should be treated from the outset with inunctions of mercury and large doses of iodide of potash. I believe that both these drugs should be employed together, even in the tertiary stage of syphilis, and it is my experience that all syphilitic nervous lesions, whether central or peripheral, yield more promptly to their combined use than to the employment of either alone. Malarial cases must be treated with quinine or Warburg's tincture. In non-malarial cases quinine has proved of no avail. In cases which are due to poisoning of any kind the first necessity is to eliminate the toxic agent from the system, and the second to prevent any further ingestion of the poison. Iodide of potash aids in the elimination. The second indication is easily fulfilled when arsenic or lead are the toxic agents, but when the case is due to chronic alcoholism special precautions are needed. Alcoholic cases require from the outset special treatment. The condition at the time of the onset of the paralysis may be one verging upon delirium tremens. If all alcohol is suddenly removed, without due care to supply some other heart-stimulant and to secure the perfect nutrition of the patient, serious collapse may ensue. The first necessity is therefore to take care of the general condition of the patient. If this will admit of the immediate withdrawal of all alcoholic stimulation it should be done; if not, the alcoholic beverage must be immediately reduced in quantity, and as soon as possible wholly cut off. The use of milk diet, or kumyss, or pancreatized milk, or, if necessary, rectal alimentation will be followed by a gradual recovery of the power of assimilation, and as soon as the patient ceases to lose weight all alcohol may in any case be safely stopped; its elimination by the intestines and kidneys may be hastened by appropriate means, and cerebral symptoms, if they arise, may be treated as in other cases of alcoholic intoxication. But it is in the chronic stage, when the patient is gradually recovering, that the vigilance of the physician is called into play to prevent a renewal of the poisoning. It is amazing that patients who know perfectly the injurious effect of alcohol upon them should insist upon getting it. But it is done. And when these patients are surrounded, as is often the case, by sympathizing friends, or servile domestics, or unscrupulous nurses, who do not appreciate the importance of total abstinence either for themselves or for the patient, they often succeed in baffling all attempts to deprive them of the favorite drink. It is only

[1] Pitres et Vaillard: Des névrites périphériques chez les tabétiques, Rev. de Méd., 1886, p. 574.

when they are watched constantly by persons who can be implicitly trusted, and who have sufficient authority to cut off all surreptitious supplies that the physician can feel sure that his commands are obeyed. And this precaution is by no means needless even when it is probable that family servants are trustworthy; for the continued plead ing and remonstrance of the patients may corrupt the best of attendants, especially if accompanied by threats of discharge at a future day. It is therefore necessary to place these patients under the surveillance of trained nurses from the start, or to remove them to an institution where they are under control.

In the chronic stage the drugs which are of greatest service are strychnia and arsenic. Strychnia may be given in doses of $\frac{1}{60}$ to $\frac{1}{30}$ gr. t.i.d., and it is well to combine it with phosphoric acid and the syrup of the hypophosphites. Arsenic may be used in tablets or pills containing $\frac{1}{50}$ to $\frac{1}{30}$ gr. t.i.d., or in Fowler's solution, five to eight drops t.i.d. The use of iron with these two drugs will be indicated in the majority of cases where there is attendant anæmia. In alcoholic cases both arsenic and strychnia may increase the mental irritability, but should be continued unless this becomes too great. I have seen benefit from both of these drugs, and think it well to employ them alternately, using each for about two weeks at a time.

The remedies used in the chronic stage have two objects: one is to increase the rate of repair in the nerves; the other is to keep the nutrition of the muscles as good as possible. While the drugs mentioned probably meet the first indication there are other remedies which meet both. These are massage, warm baths, and electricity.

The proper manipulation of the limb increases the circulation in it. The increase of circulation brings fresh supplies of material to the nerve which is undergoing repair; it also aids the nutrition of the muscle, which would otherwise be decidedly affected by the sluggish flow of venous blood, due to the lack of functional activity. As soon, therefore, as the active progress of the disease is checked and the muscular tenderness has sufficiently subsided to allow the limbs to be rubbed, this potent remedy should be employed daily.

Allusion has already been made to baths and douches in the early stage, for the purpose of quieting sensory symptoms. In the chronic stage the object is a different one. Like massage, warm baths and douches stimulate the circulation and aid the nutrition and reparative processes in progress. Hence they are to be used daily. And if the warm bath be given at night it will secure not only a local action but produce a general sedative effect, insuring quiet rest. In multiple neuritis as well as in many other nervous affections not due to anæmia, a warm bath at night or a warm douche to the neck and spine is far preferable to, and more efficacious than, the majority of hypnotic drugs in causing a good night's sleep.

The last agent to be mentioned is electricity. It is, however, among the first in importance, and in its use it is necessary to know what object is sought in its application. There is first the object of increasing the progress of nerve regeneration. This may be attained by the application of a constant galvanic current to the degenerated nerve, passing the current through the nerve in either direction, or in both alternately. A mild current should be employed, its strength being measured by a galvanometer. The strength of the current will depend: (*a*) on the size of the sponges placed upon the skin, (*b*) on the pressure upon the sponges, (*c*) on the resistance of the skin, and (*d*) on the number of cells of the battery used. If the sponges are two inches in diameter, six milliampères is enough; if they are three by five inches in measurement, twenty milliampères should not be exceeded. If no galvanometer is used the strength of the current employed is uncertain. But it is to be remembered that the current grows stronger the longer it passes, since the skin resistance is gradually overcome; and therefore, if the strength is measured in cells, the number of cells used should be decreased gradually during the application. As so few practitioners use a galvanometer it may be well to state that with large sponges (*i.e.*, three by five inches) wet with warm water a freshly filled bichromate of potash battery will give nearly one milliampère of strength for every cell used during the first three minutes, provided the sponges be put on any part of the body except the soles of the feet or the palms of the hands, and pressed firmly upon the skin. After the first three minutes the body resistence decreases, so that when twenty cells are used to start with, one should be cut off every half minute until the number is reduced one-third. The duration of the application should be about ten minutes to each limb. During this time the distal sponge should be passed over various parts, so as to include all the nerve-branches in the current; the central sponge should be put over the nerve-trunk high up on the limb. The current should be begun and stopped gradually, and never suddenly broken; applications may be made daily.

The second object to be obtained is to re-establish the conduction of impulses in the regenerated nerve. This is secured by the method just described. It may be attained by the use of faradism, the interrupted secondary current being sent along the nerves by placing one pole over the nerve-trunk and passing the other over the skin of the limb. The strength used should be just sufficient to be felt distinctly through the palms of the operator's hands. The third object sought is to maintain the nutrition and function of the muscles by exercising them, and thus preserving their normal irritability. This cannot be done by a faradic current as long as they do not contract to it. The galvanic current must therefore be employed. But now it is not a steady current which is needed, for this does not cause any motion. It is only when the steady current is suddenly broken and renewed that the contraction occurs. Hence place one pole over the trunk of the nerve and the other upon the muscle, and with an interrupting electrode make and break the current at the pole which is on the muscle. The pole which produces a contraction with the least current possible is the one to be applied to the muscle. This is in RD the positive, in normal conditions the negative pole. Each muscle should be exercised for three or four minutes every other day. When electrical treatment is thus employed very marked improvement is observed, which can be measured accurately if a galvanometer is used, since every week will show a change of the strength of current needed to produce muscular contractions toward the normal.

The treatment must be kept up, in the chronic stage, until recovery is complete.

If contractures have occurred in the paralyzed limbs persistent massage may overcome them. If it does not, they are to be treated on general surgical principles.

A HELP TO THE TEACHING OF PHYSICAL DIAGNOSIS.

By J. CLIFTON EDGAR, M.D.,
HOUSE-PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK.

Remembering the difficulties encountered in mastering physical signs as a student of medicine, and recognizing like difficulties daily occurring among the students of the various classes in physical diagnosis held in Bellevue Hospital, I have been led to devise some means for the more rapidly and surely acquiring the knowledge sought.

In a class, say, of thirty students, and with some ten or fifteen interesting cases to "go over" in an hour, it is very possible that many students, while occupied in the examination of an individual case, will lose the demonstration of another of equal interest by the physician conducting the class.

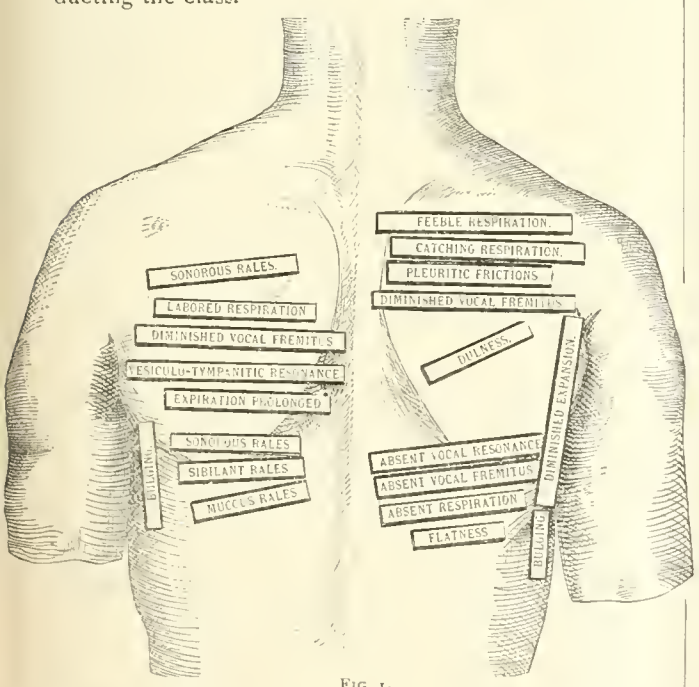

Fig. 1.

Thus, when a student, as above, comes to a patient he has failed to hear percussed or seen palpated, he is uncertain in his own mind of the signs present, and the demonstration has to be repeated.

To do away with this difficulty it has been my custom, as assistant to Professor A. L. Loomis in his class of physical diagnosis, to label each patient, after Professor Loomis has made his examination, with the name or names of the particular conditions present, these conditions being detected by inspection, palpation, percussion, etc.

For this purpose small strips of rubber adhesive plaster have been printed, with the various signs of thoracic and abdominal disease, as indicated by the above mean of diagnosis.

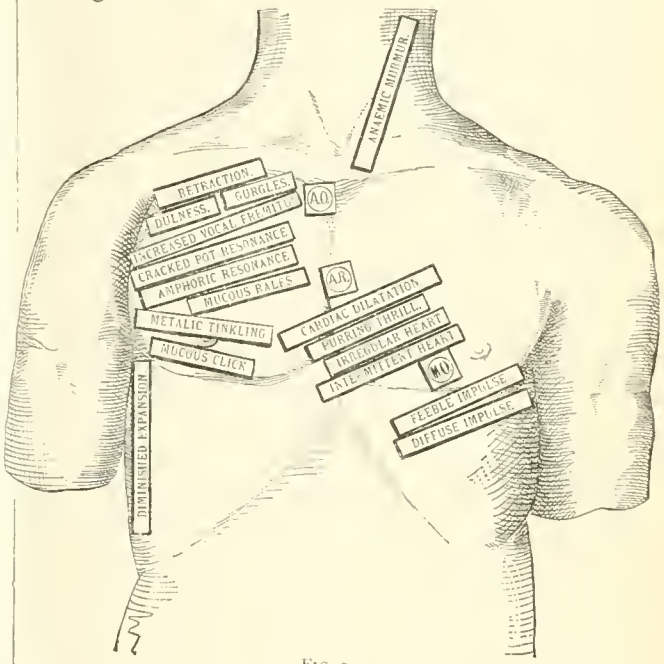

Fig. 2.

The lettering is in clear block type, very compact. and the plaster adhering so closely to the surface, and being so small in area, there is no danger of its giving rise to abnormal sounds or obstructing the examination.

For example, after the physical signs contained in a perfectly normal chest are mastered, a case, say, of emphysema, is taken.

This case is examined by a practised ear, labelled with the signs found, and handed over to a student to go over at his leisure.

Another case, say of general bronchitis, is treated in a like manner. The student is thus certain in his own mind as to what the sounds heard within the chest signify. Having once heard a certain normal or abnormal sound, he is pretty certain to recognize it in the next instance without any such aid.

The accompanying cuts explain themselves. Fig. 1 would represent some of the signs to be found in a man having a large cavity at the upper part of his right lung, together with cardiac dilatation with murmurs at aortic and mitral orifices.

Fig. 2 would represent the posterior surface of a man's chest having a pleurisy with effusion on his right side, and emphysema and bronchitis of his left lung.

An Inebriate Asylum in Italy.—In 1882 there was established in Milan a temperance society, the first and only one in Italy, called the Patronato di Temperanza. As an aid to its work of reform the society has determined to establish an asylum in Milan for the reception and care of inebriates desiring to be cured of their affliction, and for this purpose has issued an appeal to the charitably disposed in that city for assistance.

A Curious Remedy for Typhoid Fever.—The New York correspondent of one of our exchanges, in a notice of the treatment of typhoid fever in the different hospitals, says that at Mt. Sinai Hospital Catholics are omitted in this fever. We never heard of Catholicism being a very efficient antipyretic, except perhaps as a long-range prophylactic, and we presume the author wrote cathartics.

Progress of Medical Science.

A Case of Nervous Contagion.—Dr. Kreuser relates the clinical history of a family which furnishes a curious example of induced mania. A girl, eighteen years old, began to suffer from religious melancholia, with delusions of obsession, and having no treatment soon became insane. She passed whole days and nights praying and making her parents pray also. A few days later the family shut up the doors and windows, and all sat around the table with Bible and Prayer-book before them. The father and mother pounded on the table with their fists and cried continually: "If it is right, so must it be." Everyone who tried to enter the house was driven away with blows. The most violent of all was the younger sister of the patient first seized. Finally the neighbors became alarmed at the state of things and made a regular assault upon the house, finally gaining admittance, and then carried the inmates off to a hospital. Here the patients gradually became quiet, and were restored one after another.—*St. Petersburger Medicinische Wochenschrift*, No. 36, 1886.

The Treatment of Pleurisy in Children.—Dr. Wiederhofer has recently studied this subject, chiefly from a clinical stand-point. The following are the main points of his paper, as given by the *Archives of Pediatrics:* The younger the child the more difficult of diagnosis is pleurisy. The disease may be entirely overlooked without a very minute examination. After the exudate has formed the diagnosis is somewhat less difficult. Then the child breathes more superficially, there is a febrile movement and cough, which may last several days. The frequent and superficial respiration are the more important indications in making the diagnosis. If there is no exudation in the pleural cavity, the child will lie upon the diseased side. As to the physical signs, at first there is general bronchial respiration, gradually there is dulness on percussion and diminution of the respiratory murmur. Should the exudation be abundant the diagnosis may be readily made, but should it be limited to a small area at the base of the pleura the diagnosis will be difficult. The sensation which is yielded by percussion is believed to be of greater assistance in forming a diagnosis than the information which is obtained by auscultation. The prognosis of this disease among children is usually favorable. Thoracentesis will be necessary in case the exudation is not absorbed, and especially in cases in which it is so abundant as to occasion troublesome dyspnœa to the patient. Purulent accumulations rather than serous or serofibrinous ones cause trouble of this kind, and can usually be correctly diagnosticated in those cases in which an exudation persists longer than fifteen days, the temperature reaching 104° F., morning and evening, while the child steadily emaciates. The crucial test is, of course, an exploratory puncture. The treatment of purulent pleurisy by aspiration is not followed by the best results, for, in a few days, another deposit of pus has taken the place of the former one. The author believes that it is best treated upon the same principle which governs the treatment of abscesses. An incision, sufficiently large, is made between the fifth and sixth ribs, the pus is evacuated, a drainage-tube is introduced, and an antiseptic dressing applied. The patient is usually cured in from two to three weeks. Should the operation be deferred until an advanced period of the disease the pleural cavity must be washed out systematically with a solution of salicylate of soda or of thymol. Phenic acid solutions are dangerous, and numerous cases of poisoning have followed their use. Unless the operation is performed early there will be deformity of the thorax. If the purulent deposit is left to itself it may point somewhere upon the abdominal or thoracic wall, and will be revealed by swelling, fluctuation, and inflammatory œdema. In most cases of this character there is a fatal issue.

Nocturnal Cough in Children.—Sharp paroxysms of cough, which sometimes suddenly attack children at night when they are apparently enjoying the most tranquil sleep, are believed to be due to the accumulation of salivary and mucous secretions of the mouth, originating from a stomatitis or gingivitis which is associated with dentition. As the patient lies in the horizontal position the accumulated secretion tends to gravitate toward the epiglottis, the arytenoids, and even to the posterior commissure of the larynx. Thus the rich reflex nervous supply of this region is excited, and a cough, either convulsive or non-convulsive, is the result. During the day, when the child is in the horizontal position, the same conditions do not obtain. The same condition as to accumulation of secretions is seen in chronic and moist coryza. McCoy thinks that the paroxysmal cough in question is always the result of nasal catarrh, and is due directly to an irritant action upon certain zones of mucous surface in the nasal fossa, which were described by Hack, Mackenzie, and others. According to McCoy's explanation the vertical position enables the secretion to escape readily by the natural channels, while at night the dorsal decubitus prevents such a course.—*The Archives of Pediatrics.*

Quinine by Inunction.—It is often stated, and as often denied, that an ointment of sulphate of quinine and lard proves promptly efficacious in acute malarial affections. Those who affirm speak from experience, while those who deny the fact speak upon purely theoretical grounds. Liebreich is quoted as saying in a public address that Unna's experiments upon the relative affinity of different oils and fats for water determines the degree or capacity of such for cutaneous absorption. Hence it is argued that, as sulphate of quinia is very sparingly soluble in water, and not at all so in lard, an ointment made of these could not penetrate the dermis. After a tepid bath the ointment of quinia and lard may be rubbed into the skin of infants and others who are unable to tolerate any form of antiperiodic in the stomach, with promptly efficient results, theoretical objections to the contrary notwithstanding. The great discrepancies of opinion as to proper dosage depend, no doubt, upon two widely varying conditions: One as to the urgency of the demand for antiperiodic effects; the other as to the thoroughness with which all the details of the administration, in order to secure its introduction into the general system, are observed. Any form of inunction presupposes a freshly bathed surface for application, and any form of disease demanding quinia is sufficiently urgent to require enough of the drug to make its powerful impress upon the nerve-centres, as evinced in diuretic and diaphoretic stimulation. All the good effects, with the least of the bad effects of quinia, can best be secured in one full dose at night.—*Progress*, December, 1886.

Twenty Cases of Alexander Adams' Operation.—Dr. W. Gardner, in the *Australian Medical Journal*, October 15, 1886, publishes a series of twenty cases in which he performed the operation for shortening of the round ligaments. In no case did the operation result in death. The first case operated on was a complete failure, owing to imperfect performance of the operation, due to want of knowledge. Of the rest, one has been found to continue well three years after operation, two for a period of two years, seven for a period of one year, nine for a less period than one year. Four of them have been delivered of living children at full time. His method of operating and after-treatment is as follows: He draws out the ligaments from four to six inches, and always ties them together over a large pad of gauze. He also sews them carefully to the margins of the ring and to the skin. He uses very little sedative, and gives only ice to suck for the first twenty-four hours. Urine is allowed to be passed spontaneously to avoid the risk of cystitis. The first change of dressing is generally made on the seventh day; up to this time Lister's gauze

is used, and afterward iodoform and salicylic wool. The patient is allowed to get up and sit in a chair, or recline on a sofa, at the end of the third week, and is encouraged to walk after the fourth week has passed. No pessary or artificial support is used. He is inclined to believe that the operation will be found most beneficial in cases of chronic retroflection, with prolapse of one or both ovaries, the fundus being made to describe an arc of a circle which shall prevent it from pressing on the ovaries. It must also act beneficially by restoring the circulation in the broad ligaments to the normal condition. In anteflexion also it may be beneficial by straightening the uterus, and in prolapse also it will be of advantage, in cases which have resisted other methods of treatment. He inclines very strongly to the belief that displacements of the uterus are of no importance in themselves, and that they only give rise to trouble through the alterations they sometimes cause in the circulation through the broad ligaments. Therefore he does not operate because of the flexion, but only in cases where the flexion has caused alterations, probably in the circulation, evidenced by ovarian pain and reflex nervous manifestations.

Fissures of the Tongue.—In some persons, especially where gastric disturbances are present, the tongue suddenly becomes fissured all over, without, however, becoming coated, changing its color, or losing its moisture. Professor Schwimmer had the opportunity to experiment on some cases of this kind at his clinic. He tried chromic acid, which has been recommended by Vidal, and iodoform, which Dr. Unna, of Hamburg, has greatly praised, but in none of his cases did the tongues show any improvement. If anything, they became worse, especially under iodoform. As the patients were greatly annoyed by this morbid state of their tongues, the author tried a series of remedies in the hope of bringing about some alteration, but utterly in vain. Even Kaposi's treatment with nitrate of silver was useless. Some improvement was noticed after the application of soda solutions. Lactic acid, first employed by Schiff, gave the patients decided relief, and in one case almost established a cure. Finally Schwimmer used papayotin, and the result was surprising. In every case an amelioration was at once noticed, and within a few weeks a perfect cure was obtained. He applied the papayotin as follows:

℞. Papayotin..... 1 to 2 parts.
Aq. destill.,
Glycerin ..... āā 10 parts.

This solution is applied with a camel's-hair brush, from two to six times every day, after the parts have been previously well dried. The effect is not a macerating one, as one would think from the action of the drug on digestion, but it acts by stopping the pain in the parts deprived of their epithelium, and causes a renewal of the latter. In twenty-five cases, many of which were of many years' duration, a complete and permanent cure was established in all, with the exception of one, where a syphilitic dyscrasia existed, but where specific treatment brought about no result either. But even in this case a great amelioration was obtained.—*Wiener Medizinische Wochenschrift.*

Fracture of the Base of the Cranium.—Frederick Hyde concludes his consideration of the above subject with these suggestions: 1. The anatomy and physiology of the base of the skull render its fracture more fatal, independently of their inaccessibility to direct surgical treatment, than when the lesion is restricted to the cranial vault. 2. The symptoms determining the diagnosis in basal fracture are caused by meningeal and cerebral lesion involving the origin of nerves or their continuity, often both, as well as lesions of blood-vessels. 3. While the displacement of fragments in this fracture is but little in the majority of cases, it will be more in the minority; and it is not uncommon, when the displacement is not detected in the outer table, that the inner will be comminuted and the fragments lodged in the subcranial tissues, with blood extravasation. 4. In the majority of examples of this fracture the symptoms of cerebral pressure are plainly marked; if not early, they appear only a little later, and yet so early as to prove that they are the immediate result of the injury, rather than from inflammatory products which appear later. 5. When the fracture involves the lower part of the parietal bone and the temporal with its petrous portion if compound, or only contusion of the part receiving the blow or force with marked symptoms of this fracture, an incision made at or over the site of the bruised scalp will aid in detecting the extent of the injury. 6. If fragments of bone or blood can be reached, remove them; and if there be slight or greater displacement, with positive symptoms of pressure which cannot be removed, then apply the trephine, elevate the depressed bones, and if there be blood remove it. 7. In this fracture, when caused by the direct application of force, as may be in the frontal sinus and in the proximity of the base of either fossa, with positive symptoms of brain-pressure, the hopeless condition of the case left to the expectant treatment, if there be no opening through the soft coverings of the bone at the point receiving the injury, warrants making an incision for exploration, that its cause may be better defined, and if it cannot be removed without, then use the trephine. 8. In all cases, if the operation of trephining is to be made, it should, as in vault fractures, be done at once after the receipt of the injury, to shorten the time of pressure upon the vital textures, and before inflammation has occurred.—*Medical Times.*

What to do in Puerperal Eclampsia.—Dr. Clarkson, in the *Virginia Medical Monthly* (October, 1886), sums up his views on the treatment of eclampsia as follows: Encourage the attendants. Enforce quiet. Restrain your patience sufficiently to keep her from bodily injury. Place a cork between her teeth. Remembering that the whole surface of the body is in a condition of hyperæsthesia, make as few vaginal examinations as possible. Use the catheter only if there is distention of the bladder. At no time yield to the common suggestion to apply blisters to the nucha, or cataplasms to the calves. Evacuate the bowels by stimulating enemata. If there has been constipation, purge by calomel or croton-oil. Apply cold to the head, and remove hair if necessary. Mustard-baths to the feet. Do not dash cold water into the face. It may be done in hysteria; in syncope it is undoubtedly beneficial, but in eclampsia, Barnes says, "he has seen it provoke a fit, and knows it to be decidedly injurious." Give enemata of chloral and a bromide. Bleed only in decided plethora to relieve cerebral hyperæmia. Etherize, but not completely, except during a paroxysm. Keep your hands off your patient, save when necessary to perform some service, and then, if possible, do what is to be done under the cover of anæsthesia. The spasm over, prepare to empty the uterus. Puncture the membranes and leave the rest to nature. If nature refuses to respond, slowly dilate the os. Do not forget that the fingers in cone shape are the best dilators, and chloral their best assistant. Dilatation effected, deliver with the forceps for the head, or, in breech cases, by the feet. The uterus emptied, all unfavorable symptoms will vanish; if not, continue the chloral, the bromides, etc., as needed.

Cremation in Denmark.—The Danish authorities have forbidden cremation on the strength of an old ecclesiastical law passed in 1685, according to which burial is prescribed as the only way to dispose of the dead. As a crematory has already been erected in Copenhagen the owners feel that they have a just cause of complaint that they were not earlier informed of the existence of this law.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 12, 1887.

INHALATIONS OF COLD AIR IN TYPHOID FEVER.

COLD air has been used to a limited extent for the reduction of elevated temperatures, but it has not found much favor among therapeutists, and has never attained the position among antipyretic agents that cold water has assumed. Yet, if we may rely upon some experiments made by Dr. Sokoloff, related in the *Journal de Médecine de Paris*, this would seem to be a remedy of no little power in depressing an abnormally high body temperature.

Dr. Sokoloff noticed that patients with typhoid fever who were treated in hospital tents during a season when the temperature at night would fall nearly to the freezing point were almost apyretic in the morning, although in the evening they might have a temperature of 104° F., or over. This observation led him to institute a number of experiments to determine the effects of the inhalation of cold air in fevers. He used the inhaling apparatus of Niemeyer, and gave three inhalations a day, of from five to thirty minutes' duration. The temperature of the inspired air varied from 16.5° F. to 26.5° F. Thirty-three patients with typhoid fever were subjected to these experiments, and from the results observed the author came to the following conclusions:

1. Inhalations of cold air cause a reduction of temperature, less marked, however, and less constant, than that obtained by baths of cold water, or even of cold air. The antipyretic effect varies according to certain conditions—(*a*) The time of day: the most marked depression of temperature was obtained when the inhalations were given in the early evening. (*b*) The stage of the disease: the most noticeable results were obtained after the second week, the fever at this time being often reduced 2° F., and remaining low for several hours. (*c*) The duration of the inhalation is not of much importance, though the best effects were generally observed when this had been prolonged over a period of about fifteen minutes. (*d*) The temperature of the inspired air: the most noticeable results were obtained when this was between 16° F. and 20° F. (*e*) The moral condition of the patient: in states of great mental depression or excitement the antipyretic action was much less marked.

2. Inhalations of cold air cause a reduction in the number of respirations of about four in the minute, and in the cardiac pulsations, of about six.

3. They diminish the unnatural dryness of the skin and mucous membranes.

4. They exert a favorable influence upon the bronchitis which so often complicates typhoid fever, and cause a more rapid exchange of gases in the lungs.

5. In consequence of this, they lead to an improvement in the general condition of the patient, and produce sleep.

6. The inhalations act as antiphlogistics upon the inflamed respiratory passages, and may be used with advantage in the treatment of chronic bronchitis, asthma, and emphysema.

The use of cold air as a therapeutic agent has been tried by Senator, Niemeyer, Rosenthal, and others. Traubenberg has made a number of experiments with cold-air baths, but considers them as inferior in value to baths of cold water. Sokoloff, in his experiments, never saw collapse induced, nor were there any other complications which could justly be attributed to the inhalations. The method, were it found to be really efficacious, would commend itself by its ready applicability, in winter at least, since air of the required temperature could at once be obtained from without, and there would be no necessity for moving the patient from the bed to the bath and back again, with its attendant risks.

The plan of treating patients with typhus fever in tents or open barracks was at one time extensively employed in this city, with very good results. And whether the good effects observed were attributable to the fresh air and thorough ventilation, or to the cold inhalations incidentally administered, is a question which might suggest itself. The method is probably not devoid of danger, especially as regards congestion and inflammation of the bronchial mucous membrane, and experience only can show whether the risks would be counterbalanced by the beneficial results obtained.

TEMPERANCE AND DRUG STORES.

KANSAS, among other things, enjoys the distinction of being a prohibition State. Its legislators have provided it with an enactment known as the "drug-store law." The Osage City *Free Press* has recently taken the trouble to investigate the working of this law, and to what extent prohibition prohibits under its salutary provisions. One of our leading dailies has shown its interest in the subject by some judicious editorial comment relative thereto. It appears that, in a general way, the law has been a great boon to the business interests of the druggist. The "saloon" still exists, but it has now assumed the more tempting guise of the pharmacy. To procure the coveted liquor the would-be consumer need not, as in some States, flourish a physician's prescription in the face of a perhaps unwilling clerk. The Kansas citizen dispenses with that empty formality, for the statute allows him to be the sole judge of his alcoholic needs and requirements. The local paper above named "has prepared a curious and strikingly significant table giving a full list of the purposes for which liquor was sold in that county during the month of June last. It is an extraordinary exhibit. Three hundred and fifteen different reasons for wanting liquor are given, and the majority of these are of a character to satisfy the reader that the assumption of medical

uses was the shallowest pretence. Thus we find people demanding whiskey for bilious headache; for a broken arm; for spinal complaint; for bathing; for chronic diarrhœa and chronic constipation; for congestion of lungs; for dropsy and heart disease; for a mysterious complaint styled 'dry stomach;' for epilepsy; for gravel; for inflammation of the kidneys."

The New York *Tribune* continues: "It is wonderful how the thoughtfulness of the Osage County citizens is developed by the drug-store law. The number of men who wanted whiskey for their wives, for their children, even for sick babies, is truly surprising, while the humanitarian spirit is further shown in the eagerness with which the same remedy was sought for the special benefit of sick cows, mules, colts, and horses."

The Kansas law-makers are doubtless gratified to perceive how completely the objects aimed at by their measure are fulfilled. On the principle of *similia similibus curantur*, whiskey is certainly a sovereign remedy for "headache." A refractory druggist may, perhaps, believe that "the remedy" is not invariably suited to the particular "disease" for which he sells it. But the law gives him no power to exercise his own discretion. So that the man who suffered from "indigestion of the lungs" got his "medicine" just as promptly as if he had pleaded the wants of a sick baby or a sick mule. "In fact, the table cited proves that, if the Kansas saloons have been closed, the drug stores have taken their place quite effectively, and that so long as the present drug-store law remains on the statute books nobody is in any danger of suffering from 'dry stomach.' The *Free Press* has done public service in compiling these interesting and unique statistics. They constitute a revelation, for they indicate that in a so-called prohibition State there has been enough liquor influence to enact legislation which practically knocks the bottom out of the prohibition policy of the commonwealth. Such a drug-store law as that of Kansas is in effect a free liquor measure, and this the table of the *Free Press* completely demonstrates. Anybody and everybody can procure all the liquor they want in any part of Kansas, the only change being that they have to get it from an apothecary instead of a saloon-keeper. Of course it is nonsense to discuss such a state of things as having any definite relation to a real temperance movement."

We have nothing to add to this quotation, except to emphasize the fact, attested by ample experience, that repressive legislation has hitherto given us no more real temperance, than attempts to extinguish prostitution "by law" has given us universal chastity. It may be discouraging to have to write this, but the evolution of "man" from "animal" has evidently not yet reached the high latitude of immunity from vicious propensities. Until that millennial period, however, it is to be feared that the experience of the Kansas law-makers will be from time to time repeated.

TUBERCULAR CONTAGION THROUGH THE MEDIUM OF CHICKENS.

It seems to be a fact pretty conclusively established that tuberculosis can be transmitted by milk and infected animal food of certain kinds, though examples of the latter method of contagion are not as yet very numerous. An instance of this nature, of considerable interest and not without practical importance, was recently communicated to the Société des Sciences Médicales de Gannat by Dr. de Lamallerée.

In a little hamlet of ten cottages, isolated in the midst of a large forest, and always hitherto free from any cases of tuberculosis, a young soldier returned home affected with pulmonary phthisis. His wife also became tuberculous and gave birth to a child who speedily showed evidences of hereditary tuberculosis. Another woman in the same hamlet presented in her turn the evidences of pulmonary phthisis. She had had no intercourse with the first cases, but had eaten of eleven chickens which had died in the yard of the soldier's house. The chickens were cooked very little before being eaten. The autopsy of another of the same flock showed tubercular lesions of the intestines, and the tubercle bacilli were found in great numbers. These chickens would thus seem to have been the means of conveying the specific virus, having themselves become tuberculous from eating the sputa from the affected individuals.

This observation possesses a threefold interest, as showing the possibility of transmitting the contagium of tuberculosis from man to man, from man to animals, and from animals to man.

News of the Week.

The Naval Medical Service Again.—The daily papers are taking up the complaints made about the United States Naval Service. There are ten vacancies in the grade of Assistant Surgeon in the navy, which have existed for more than a year. It is with the utmost difficulty that suitable young physicians are induced to enter the service. The Board of Medical Officers at Philadelphia, in its annual statement, says that of thirty-nine candidates examined for appointment as Assistant Surgeons, only seven proved successful. This year the Board has as yet done no work, but will examine several applicants on the first of next month. The Surgeon-General regrets exceedingly that the superior advantages offered physicians to enter the medical corps of the army, leave but few desirable ones from which the navy can choose. The pay of an army Assistant Surgeon, immediately upon entering the service, is that of a First Lieutenant of cavalry. In the navy it corresponds with that of a Second Lieutenant of infantry. In the army the new Surgeon has good quarters, while in the navy he is obliged to dwell in the steerage. Surgeon-General Gunnell deplores this condition of affairs, and intends to make it one of the first objects of his administration to place the medical corps of the navy on a footing with that of the army. We wish him every success.

Dr. Luther M. Knight died at Franklin Falls, N. Y., February 2d, aged seventy-seven years. He was born in Franconia, and graduated from Dartmouth Medical School.

Dr. C. C. Rice.—The Trustees of the New York Post-Graduate Medical School and Hospital have elected Dr. Clarence C. Rice Professor of Diseases of the Nose and Throat, in the place of Dr. Clinton Wagner, resigned.

Decided Megalocephalia.—The brain of the late Professor Edward Olney, of Michigan University, is stated to have weighed sixty-one ounces. This weight is rarely exceeded, the records giving not more than four or five instances. Abercrombie's brain weighed sixty-three ounces, and Schiller's the same.

The Washington Irving Bishop Performances.—Those who have seen Mr. Bishop perform his extravagantly advertised "mind-reading" performances will be astonished most, perhaps, to think that so much discussion has been excited by them. His tricks are, with hardly an exception, manifest examples of muscle-reading, and can easily be explained upon that theory. Mr. Bishop has undoubtedly an extraordinary muscular sensitiveness, which has been highly trained; but as for mind-reading, he does none of it.

A Prize Essay on Hay-Fever.—A prize of $25 is offered by the United States Hay-Fever Association for the best essay on hay-fever, its pathology, causes, and treatment. The essay is to be practical and non-technical. Manuscripts are to be sent to Samuel Lockwood, Freehold, N. J.

The New York Obstetrical Society has become semi-public, *i.e.*, its meetings are no longer to be held at the houses of the members, and outsiders, to a limited number, can attend on invitation of the members. We agree with the New York *Medical Journal* that the change is "certainly experimental," and we fear that the prestige of the society will wane.

The New Hospital for Phthisis and Incurables, to be erected in this city at 144th Street and St. Ann's Avenue, will contain 250 beds and cost $150,000.

The Celebrated Gynecologist, Professor Schoeder, recently died in Berlin.

New Medical Journals. — The *Foreign Medical Press* is the title of a new journal recently started in this city under the editorship of Mr. J. L. Stern. The *American Journal of Psychology* is announced to be edited by G. Stanley Hall, Ph.D., at Johns Hopkins University.

The Tallest Man of Modern Times has recently been put on exhibition in London. His height is given as eight feet nine inches, which is about a foot higher than any other modern giant.

For Corns and Bunions an efficient remedy is equal parts of castor-oil and tinct. iodine. This is to paint on the part two or three times a day.

Beer and Health.—An alliterative organization, called the "Brewers' Benevolent Bureau" has instructed its physicians to examine 1,000 employees in the breweries as to their morbility, mortality, and general physical condition. These men drink three or four quarts of beer daily. Of the 1,000 only 2.5 per cent. were unsound, 7 having liver and 5 kidney disease, 1 heart disease, 1 phthisis. The death-rate was lower by forty per cent. than the average in an adult city population, and, altogether, the conclusion is to be drawn that the drinking of several quarts of beer daily is promotive of health and longevity. This is an instance, however, in which every-day experience quite overrides statistics.

Sexual Physiology and Mohammedan Women.—Mussulman girls are circumcised, says Dr. Zambaco, *i. e.*, have the clitoris removed at the age of seven. They menstruate, as a rule, at the age of nine or ten years. They marry, as a rule, at about this time, or even before, and the result is uterine disorder and a very small fecundity. Mussulman women have a horror of pregnancy, and abortions are common. Their whole life is centred about the sexual sense and its gratification, and the results are early maturity, slight fecundity, shorter duration of physical beauty and sexual life. Our esteemed but unwarmed contemporary, the *Boston Medical and Surgical Journal*, says: "The harem and the higher education may lead by widely divergent paths to a common goal, sterility."

The Excise Commissioners have assigned the sum of $113,000 to be divided among the charities of this city.

A Bill to Exempt Hospitals and other charitable institutions from paying the water-rates has been introduced into the State Legislature.

Intubation of the Larynx, Descent of Tube, Removal by Tracheotomy; Recovery.—Such is the history of a case reported by Dr. Joseph Eichberg, in the *Cincinnati Lancet and Clinic*. The tube did its work well, but when the symptoms had so improved that it was desired to remove it, the instrument, being of the old pattern, was pushed down and had to be removed by an operation.

Two New Medical Journals have recently reached us, viz.: *Zeitschrift für Nahrungsmittel-Untersuchung und Hygiene*, a monthly journal published at Vienna, and edited by Dr. Hans Heger, and the *Centralblatt für Bacteriologie und Parasitenkunde*, edited by Dr. O. Uhlworm, of Cassel, and published by Dr. Gustav Fischer, of Jena.

The Dark Side of Florida is said to be malaria and mosquitoes, both being more or less prevalent in most sections of that sunny State.

In Active Laparotomy of 347 gynecological cases presented to the Liverpool Hospital for Women, 167 were treated by abdominal section.

The Hospital Saturday and Sunday Fund had, at last accounts, reached the sum of $50,304.07.

The Michigan State Medical Society holds its next annual meeting on May 12 and 13, 1887, instead of in June, as was first announced. This change is to prevent any conflict with the American Medical Association, which meets June 7th to 10th.

Physicking the Paupers of Llanfihangelrhosycorn.—A correspondent of *The Lancet* writes: "For the privilege of physicking the paupers of the parish of Llanfihangelrhosycorn and the adjoining parishes the guardians offer, forsooth, a salary of no less a sum than £30 per annum, and at the same time gently announce the acreage of the district. The area of the combined parishes is stated to be 34,700 acres. The advertisement calls to mind some lines of Albert Smith:

"'The parish is small—ten miles by sixteen,
With some commons and gravel-pits scattered between;
And respecting the cases, to state 'tis p'r'aps right,
That they always occur at the dead of the night.'"

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 3, 1887.

ABRAHAM JACOBI, M.D., PRESIDENT, IN THE CHAIR.

AFTER the reading of the President's address, DR. JOHN H. GIRDNER was introduced, who read a paper and made a demonstration

ON DETECTING AND LOCATING METALLIC MASSES IN THE HUMAN BODY BY THE INDUCTION BALANCE AND THE TELEPHONIC PROBE.

The author first referred to the apparatus constructed by Professor Bell for detecting the bullet in President Garfield's case, an experiment which failed because of the haste in its preparation, and because the patient was lying upon a metallic mattress, unknown at the time, which interfered with the proper working of the instrument. Dr. Girdner said that now, however, we have before us a perfected apparatus, one which will detect and locate any piece of metal, wherever situated in the human body. It would prove particularly useful in times of war. The second apparatus, which he ventured to name the telephonic probe, was also the invention of Professor Bell, and was useful in connection with the induction balance, as by it the exact distance to the ball could be determined.

In the construction of the induction balance a bichromic battery was used, with six cells, and an ordinary interrupter, the interruptions being about six hundred to the second. The exploring coils were put in a framework of wood, which he called the explorer, while to the others the name adjusting coils was given. Thus in the primary current were two coils, in the secondary current were also two coils, and in the circuit was a telephonic receiver. When the exploring coil was not in relation to a metallic substance there was silence in the telephonic receiver, but as the explorer approached or receded from the metallic mass the balance was disturbed, producing a musical tone in the receiver. The sound was distinct a distance of six inches from the metal, if located in the human body; a less distance if the intervening space was occupied by air or an inorganic substance.

The telephonic probe consisted of a telephonic receiver and two wires, one terminating in a long, slender steel probe, and the other being connected with a steel plate laid over the surface of the body in the neighborhood of the metallic mass, as determined by the induction balance. The steel probe being now plunged into the body (the surface having been first rendered insensitive by cocaine), as soon as it reached the metal a distinct click is heard. The practical working of the first instrument was demonstrated upon a man in whose chest a bullet had become lodged during the civil war, and of the second, upon a piece of beef into which a mass of lead had been placed. The President was also able to discover with it a quarter of a dollar in one of his pockets.

DR. NEWTON M. SHAFFER then read a paper on

THE USE OF CONTRACTION IN THE TREATMENT OF CLUB-FOOT, WITH A CONSIDERATION OF SOME OF THE MECHANICAL PRINCIPLES INVOLVED, AND A DESCRIPTION OF THE ANTERO-POSTERIOR AND LATERAL TRACTION APPARATUS.

The paper was supplementary of one previously published in the MEDICAL RECORD. Numerous diagrams were presented, showing the mechanical principles involved in motion at the ankle-joint in health, and it was a return to this state for which treatment was instituted in club-foot. The author claimed that there was only one antero-posterior centre of rotation, and that is not at the ankle-joint, but below it. The direction of the heel in flexion of the foot is downward and forward, and of the toes forward and upward. These principles should be carried out in any apparatus devised to overcome club-foot, but, in fact, the apparatuses employed ordinarily act on principles quite opposed to those which we see in nature. For instance, instead of being constructed and applied in a manner to push the heel downward and forward, and to bring the toes upward and forward in overcoming talipes equinus, they make direct traction upon the toes, fix the heel in a manner to prevent it from going downward and forward, and indeed, by the force exerted upon the toes, tend rather to bring the heel in the opposite direction, namely, backward and upward. His own instrument, based upon the principles seen in the action of the healthy foot, was then described, and also the one intended to overcome varo-equinus—instruments which he had greatly improved since his last publication. He rarely found cases which did not conform to traction treatment, and still more rarely those which did not yield to tenotomy and traction combined.

DR. RIDLON said that, after six years' experience, he was unable to obtain as good results from the lateral shoe as were obtained by Dr. Shaffer. There were certain cases in which good results could not be obtained by traction, by whomsoever applied, and he thought we ought to be able to distinguish those cases from the beginning. One indication was a sensation of shivering or shudder passing throughout the patient's entire system when the foot is placed upon the stretch.

DR. KETCH said it ought not to be forgotten, in applying Dr. Shaffer's method of treatment, to employ traction intermittently. Relapses after tenotomy were common, and the usual so-called after-treatment was rendered much less by the use of traction with Dr. Shaffer's apparatus. He had been much gratified with the results of the lateral extension shoe.

DR. JUDSON remarked that, inasmuch as Dr. Shaffer's apparatus was capable of exerting a great deal of force, he thought it should be in capable hands. He would say, but not as a restriction upon the paper, that proper treatment instituted very early ought to do away with the necessity for an operation or apparatus.

DR. SHAFFER closed the discussion, and expressed some surprise that Dr. Ridlon had found the use of his lateral traction apparatus difficult. In fact, the parents could regulate it after a few visits by the physician. It should be made to fit in the first place, and the treatment should not be hastened. Some of his best results had been obtained in cases in which Dr. Ridlon thought tenotomy was indicated, namely, pain and a shudder passing through the system on making traction with the shoe.

The President was chosen as one of the committee to consider the question of an eligible building site for the Academy, the other two, consisting of Drs. George A. Peters and F. A. Castle, having been named by the council and trustees.

In March the following resolution will be voted upon:

Resolved, That the trustees and council be and are empowered to purchase a site or building, or erect a new building, for the Academy when such a course shall be considered expedient.

VACCINATION IN CHINA.—The Chinese have, from time immemorial, made a practice of inoculating small-pox; but as those inoculated are not isolated but mingle freely with others, the result is that the disease is spread only the more widely. They have of late, however, been adopting vaccination very extensively, and it is now not at all uncommon to see notices posted in various parts of the cities informing the public where they may take their children to have them vaccinated.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 22, 1886.

JOHN A. WYETH, M.D., PRESIDENT, IN THE CHAIR.

DR. W. H. PORTER presented, in behalf of a candidate, a set of specimens, consisting of the brain, which showed marked thickening of the pia mater; the liver, which was atrophied, and the kidneys, which were cirrhotic.

DR. WESLEY M. CARPENTER presented, in behalf of a candidate, a specimen of *cystoma* of the ovary, with pyo-salpinx.

PULMONARY SYPHILIS.

DR. W. H. PORTER presented two lungs which illustrated syphilitic phthisis. In one there were at the apex two small nodules, which he regarded as gummata. The case was one of acute alcoholism, and the patient died of lobar pneumonia, beginning in the apex of the other lung. The peculiarities of the gummatous formations are that they are sharply defined, have a distinct fibrous capsule, and a cheesy centre, which, after a time, break down and ulcerate into the bronchial tubes and ultimately form cavities. Absence of tubercle bacilli is also an important fact, as well as absence of rise of temperature.

The other lung showed the same lesion more extensively, and contained neither tubercles nor tubercular tissue. It was taken from the body of a man who had been in the hospital for some time, and although both lungs were infiltrated with the process throughout almost their entire extent, and contained numerous small cavities; the patient had neither elevation of temperature nor cough with copious expectoration.

Dr. Porter had found the bacillus of syphilis, described by Lustgarten, in twenty-three per cent. of the specimens examined, and in the same specimens had failed to find the tubercle bacillus. The syphilitic bacillus had been particularly abundant in the centre of the nodules.

In answer to a question, he said that he would distinguish the syphilitic lesion from pneumonic phthisis by the distinct capsule surrounding the nodules and the formation of a large amount of interstitial tissue. In that case, also, the presence of Lustgarten's bacillus would be an important fact.

DR. H. J. SCHIFF presented a specimen of

SYPHILITIC EPIDIDYMITIS

with the formation of abscess. J. A——, twenty-seven years of age, single, and a liquor-dealer, had always been healthy except for his various venereal troubles and their sequelæ. Ten years ago he had a sore on the upper part of the penis that left a cicatrix as large as a silver quarter of a dollar. He came to Dr. Schiff thirteen months ago with almost complete retention of urine, who, with difficulty, introduced a filiform bougie, and finally, at the end of two months, was able to introduce a No. 22 French. Two months later the patient had right epididymitis following gonorrhœa, which so yielded that within a few weeks treatment was discontinued. About three months after the beginning of this attack he had another attack of epididymitis on the right side, following a fresh gonorrhœa. This yielded to treatment in eight days.

Eight days subsequently he came to Dr Schiff with a typical initial lesion of syphilis, and said that he had not had sexual intercourse since his last attack of epididymitis. Dr. Schiff concluded that the patient was doubly infected five weeks before. This was on August 24th. He applied a solution of bichloride of mercury, 1 to 1,000, and the sore healed in eight days.

On October 2d the patient came with secondary roseola. Mercurial inunction was begun. On November 1st there was commencing alopecia, besides large raised condylomata around the anus and scrotum. He also had mucous patches in the throat. The mixed treatment was prescribed, and the condylomata were painted with a solution of bichloride of mercury in ether—1 to 60.

November 10th he had retention of urine, was placed in bed, and had sounds passed until November 27th, when the urethra would receive a No. 26 French. During this time he took no medicine and felt fairly well.

On December 11th the right side of the scrotum was swollen, and the epididymitis enlarged but not very painful. The mixed treatment with evaporating lotions was prescribed.

December 19th, scrotum much enlarged and fluctuating. Severe pain of a burning character, and aspiration revealed pus. On December 21st Dr. Schiff made an incision, evacuated about six ounces of pus, found the epididymis much enlarged, and he could squeeze pus from places where it was broken down. He extirpated the testicle.

The specimen showed an enlarged and hardened epididymis, with softening in spots, which yielded pus on pressure. It was interesting as an illustration of the rapidity with which syphilis may run its course.

DR. H. J. BOLDT presented two specimens of

PYO-SALPINX,

interesting chiefly on account of the fact that the pain of which the patients complained was referred to the side opposite to that with the diseased appendage; also the disease was well-marked upon one side, while on the other the organs were apparently perfectly healthy.

The *first* was from a patient, eighteen years of age, married, and the mother of one child; no miscarriages. Menstruation began at the age of thirteen. For five months the patient complained of intense pain in the left inguinal region, backache, and cephalalgia; bearing-down pain on micturition; metrorrhagia and profuse leucorrhœa.

Diagnosis of probable pyo-salpinx on the right side, because on admission to hospital the patient's general condition was very poor and accompanied by some fever, and the right ovary and tube were enlarged and prolapsed. On the fourteenth day after the operation the patient left the hospital apparently well.

The *second* was from a married woman, thirty-three years of age, who had had three children and four miscarriages. The last child was born six years ago. Menstruation appeared at the age of fourteen. There was a history of gonorrhœa. For the last four months she has had intense backache, and abdominal pain of the bearing-down character, menorrhagia and metrorrhagia, intense pain in the left inguinal region, running down the corresponding thigh and leg, and profuse leucorrhœa. On opening the abdomen there was found, besides a parovarian cyst and a cyst in the broad ligament, a suppurating ovarian cyst, which ruptured, and the adhesions were so firm that the use of a drainage-tube was necessary. The patient was doing well.

DR. BOLDT also presented

A URETHRAL CALCULUS

removed from a boy, fourteen years of age, who gave the history of an illness beginning in 1875. At first there was difficult micturition, the bloody-colored urine escaping only by drops, with marked tenesmus. He went to Roosevelt Hospital, where he remained three months, and returned as incurable. In 1877 he began to have epileptiform convulsions. In 1878 he was admitted to Bellevue Hospital, where he was circumcised, but no relief was obtained, and his condition remained, after removal from the hospital, substantially unchanged up to December 19, 1886, he having been, in the meantime, under the care of several physicians. When Dr. Boldt first saw the patient he had a continuous desire to micturate, was pale and weak, but was able to pass his water only in drops. The meatus urinarius was unusually small, and this Dr. Boldt at first thought was the cause of all the trouble. But he discovered a small mass, apparently in the urethra, near the root of the penis, and was able to work it forward slowly until it was near the

meatus, which he then divided freely, and the calculus was removed. Could the calculus have been in the bladder near the urethral opening, and there remained without change of position, and caused all the symptoms for which he had been treated, or had it been in the urethra, where it steadily increased in size? He was inclined to the opinion that it had been from the beginning a urethral calculus.

Dr. Amidon presented a specimen of

CARCINOMA OF THE SPINE,

with the histories of two other cases of malignant disease of the spine—one being sarcoma. He regarded the cause of the pain, from which these patients suffer, as filling up of the intervertebral foramina with the new growth. There were small nodules of the malignant disease in the liver in the first case, and it had been a question whether or not the carcinoma of the sacrum and other portions of the spinal column was primary.

Dr. Mendelson said that the case was very similar to one which he saw two years ago. There was a history of injury in September, and in December the patient began to suffer from pain in the middle dorsal region, and intercostal neuralgia became the chief symptom. Finally the diagnosis of caries of the spine was made, although there was no deformity, and only slight tenderness on pressure. The patient grew worse steadily, symptoms of pressure myelitis developed, and he died six months afterward. At the autopsy a tumor was found within the spinal canal, extending from the body of the third to that of the fifth dorsal vertebra, which, by pressure, had produced great thinning of the cord. The bodies of the vertebræ were more or less involved, and there were extensive deposits in the lungs, so great that the diseased exceeded by far the normal tissue. About one month before death the diagnosis of tumor pressing upon the cord was made, because of a secondary deposit which appeared just above the sterno-clavicular articulation on one side, and there were deposits also in the skin. The case was interesting, especially with reference to diagnosis. At no time was there any deformity, although the bodies of the vertebræ were found extensively diseased; but the lack of deformity was attributed to the fact that the patient was most of the time in the horizontal position upon a water-bed.

Dr. Prudden thought that the small size of the nodules of malignant growth in the liver did not necessarily exclude the idea that they were primary, and the disease in the spinal column secondary. Primary carcinoma of the bones, it was generally conceded, occurred very rarely, and even its occurrence at all was doubtful. It was also well established that secondary malignant disease frequently progressed much more rapidly than the primary.

Dr. Prudden further remarked, concerning

THE EPITHELIAL ORIGIN OF CARCINOMA,

that two practical objections had frequently been urged to the acceptance of the view of the exclusive epithelial origin of carcinoma, namely, the occurrence of so-called primary carcinoma of the bone, and primary carcinoma of the peritoneum, pleura, and pericardium.

In regard to the apparent occasional exceptional occurrence of so-called primary carcinoma of the bone, it may be said that they are becoming less and less frequent as autopsies are being more carefully made, and nothing but the most complete examination of every part of the body in which primary cancer is wont to occur can justify the anatomical diagnosis of primary bone cancer. If such cases do occur, they may be explained on Conheim's theory of displaced embryonal remains. But the most serious objection, after all, to a belief in the exclusive epithelial origin of carcinoma, has been its not infrequent occurrence in the peritoneum and on the pleural and pericardial surfaces, because it has long been an accepted view that the great body cavity, which later became divided into the peritoneal, pleural, and pericardial sacs, was formed by a split in the mesoblast, was lined with true endothelium and hence was a connective-tissue structure. Recent researches, however, especially those of His and Waldeyer, and these were in a measure confirmed by Balfour, have shown that the great body cavity is not of connective-tissue origin at all, but is originally formed by diverticula from the gastro-intestinal canal, and is thus lined with true epithelium. This epithelium at a later period becomes greatly flattened, and has the appearance of the true endothelium, such as is found in the blood- and lymph-vessels. The analogy of the peritoneum with the lymph-vessels has seemed to find a justification in the free connection of the two by means of stomata; but the stomata are of late development after the peritoneal epithelium has changed its characters.

These considerations thus afford a most satisfactory explanation of the occurrence of primary carcinoma of the body cavities, which is no longer an exception, and no longer an argument against the exclusive epithelial origin of carcinoma. On the contrary, it affords a most excellent and striking example of the tendency of cell growth in tumors to reproduce the embryonal type.

Dr. W. H. Porter had examined the specimens in two cases of extensive disease of the lumbar vertebra, supposed to be cancerous, but it was found that the disease was sarcoma. There were also extensive deposits in the liver, lungs, spleen, etc. It seemed to him that where diffuse growths were found with disease of the spine they were likely to be sarcomatous rather than carcinomatous.

Dr. Amidon said that in one of the three cases he had reported the disease was sarcoma, but the specimen just presented had been examined by Dr. Frank Ferguson, who reported that it was carcinomatous. There were two facts of which he wished to speak, and the first was tenderness. Many, if not most physicians, argue against organic disease when there is no spinal tenderness, as much as they do for it when the tenderness is prominent. When the spine is excessively tender it is generally regarded as functional. But in all the cases of malignant disease of the spine which he had seen, and he had seen several, decided tenderness on deep pressure had been present. This point was brought to his attention particularly by a case which he saw in consultation at St. Luke's Hospital. A negro girl, twelve years old, had gradually increasing and painful paraplegia. He found a trifling knuckle in the lower dorsal region that was excessively tender, as was also the entire spine. She had been treated by an orthopedist, who argued against malignant disease of the spine because of the fact that it was so tender. The child died, and it was found that the disease involved the bodies of the vertebræ and was tubercular in character. Dr. Amidon thought that it could be said with safety that organic diseases of the spine are not necessarily insensitive to pressure, but are sensitive to deep pressure.

Another point was the extremely long period of latency in some cases. There might be a history of painful affection of the spine, extending over several years. According to his experience these cases have a long latent period, which was very apt to mislead one with regard to the true pathological condition present; malignant disease elsewhere being usually a rather acute process.

The President said that he removed a cancerous breast last March, and three months after the operation symptoms of metastasis occurred in the lumbar vertebræ. There was kyphosis between the seventh and ninth dorsal vertebræ, but there was no tenderness on pressure, and still the patient suffered the most agonizing pain from pressure on the intervertebral disks. There was no paraplegia or paresis. Dr. Janeway saw the patient, and diagnosticated metastasis to the spinal column, and said that he had seen two cases with similar symptoms.

Dr. Van Santvoord reported at the meeting, January 12, 1887, that Dr. Wyeth's patient is now suffering from pain along the eleventh and twelfth intercostal nerves; also pain along the distribution of both anterior crural and sciatic nerves, which dates to a period anterior to the removal of the breast. At the time the breast was removed these pains were regarded as neuralgic, but probably were due to organic changes in the vertebræ, thus sustaining Dr. Amidon's belief that malignant disease of the spine may remain latent for a long time.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

PHOSPHATIC DIABETES — THE SUTURE OF DIVIDED NERVES—PHYSIOLOGICAL EFFECTS OF MASSAGE—A NEW OPERATION FOR IMPERFORATE ANUS—A GENERAL SPECIAL HOSPITAL—SIR JAMES PAGET'S PRESIDENTIAL ADDRESS AT THE PATHOLOGICAL SOCIETY—TRUE LIPOMA OF HEART—SPONTANEOUS DISINTEGRATION OF A VESICAL CALCULUS—BURMESE MIDWIFERY—THE HIGHER EDUCATION OF WOMEN—A CURIOUS LEGAL CASE—THE WILSON BEQUEST—THE NEUROLOGICAL SOCIETY—A NEW YEAR'S CARD.

London, January 19, 1887.

The last week's society meetings have been full of interest. The more important subjects under discussion have been phosphatic diabetes, the suture of divided nerves, and the physiological effects of massage. At the Medical Society of London, Dr. Ralfe, long favorably known for his researches on urinary chemistry, read a paper on phosphatic diabetes. Particulars were given of thirteen cases. The cases were arranged in groups, according to the classification of Professor Teissier. All but two of the patients were young adult males. The symptoms in all were emaciation, aching pains in the loins and pelvis, dry harsh skin, tendency to boils, ravenous appetite, and, in some cases, cataract. In most of the cases there was polyuria; in others the urine was normal in quantity, but with a high specific gravity. The urea was increased—in some cases slightly, in others considerably. In all the cases the phosphoric acid eliminated was considerably—and constantly—increased in amount. Dr. Ralfe thought that the increased elimination of phosphoric acid did not depend so much upon increased metabolism of nervous matter as upon defective nutrition. When it was associated with nervous derangements or phthisis, respectively (Groups 1 and 2 of Teissier), the prognosis was unfavorable. When alternating with saccharine diabetes (Group 3), or running a distinct course by itself (Group 4), the outlook was much better. Two cases under Group 3 had got well. For measuring the amount of phosphates discharged he employed volumetric analysis, uranium nitrate being used to precipitate the phosphates. Care must be taken to use a specimen of urine from the mixed urines of the twenty-four hours.

At the Medical and Chirurgical Society an animated discussion on the suture of divided nerves followed the reading of a paper on the subject by Mr. J. Bland Sutton. Mr. Sutton maintained that by following the rules which had been gained by studying the effects of neurotomy in horses, the ends of the divided nerve could be found with ease, and then sutured. In horses, after the experimental performance of neurotomy, he had found a delicate fibrous band present, uniting the divided ends. Mr. Holmes doubted the general existence of this band, an opinion shared by Mr. Bowlby. The latter remarked that in cases where the injury was an old one, it was evident that not only the nerve, but the muscle, had to be remade. The first sign of restoration was a return of voluntary power; this might precede the return of electrical reaction by many months. He was convinced that the lower end of the nerve could be regenerated without being brought into contact with the upper end of the divided nerve. Thus it might happen that union of divided ends, even after a long time had elapsed, would be followed by very rapid return of function. Mr. Hulke asked what we were to do if the divided ends were so widely separated as to render it difficult, if not impossible, to bring the divided ends together? German surgeons had united them by pieces of sciatic nerve from sheep and dogs, and apparently with success. A method of side-splitting the nerve and bringing one piece down to fill the gap had also been used. Cylindrical decalcified bird's bone had also been tried. Mr. Warrington Haward remarked on the great variation in the time that elapsed between operation and restoration of function.

An interesting paper on Massage, by Mr. Symons Eccles, was then read. Mr. Eccles had made a number of experiments on healthy persons as to the effects of massage. He described four distinct manipulations, viz., *effleurage*, *pétrissage*, *massage à friction*, and *tapotement*. Massage was a combination of these, and its immediate and remote effects were that the texture of the skin was improved, the sense of locality increased, and the general temperature of the body raised. The surface temperature of a part under massage was higher than that of the rest of the body, while abdominal massage reduced the temperature of the extremities. A course of massage of one month increased the body-weight, the appetite, muscular strength, and ability to eat and sleep well. Dr. Hermann Weber remarked that medical men should themselves superintend the treatment. Dr. Playfair observed that he had taken more interest in the forms of the disease for which it was useful than in massage itself. As a remedial agent in neurasthenia it was most important. Many patients put on several pounds a week, and he had known the body-weight to be doubled in six or eight weeks. In a case of destructive disease of one lung eighty-four pounds in weight were gained in a few weeks. He believed that any hysterical appetite could be made by this treatment to eat, assimilate, and digest more than a Lifeguardsman could in the same time. Dr. Douglas Powell remarked on the necessity for medical supervision, and said he had known a nurse induce hæmaturia by rubbing, contrary to order, an abdominal tumor. Dr. Arthur Gamgee said there was a difficulty in acquiring all the methods. To treat infantile paralysis or scrivener's palsy by massage a thorough anatomical education was necessary. Massage could modify the condition of internal organs.

At the Clinical Society the most noteworthy paper was one by Mr. Mayo Robson, of Leeds, in which he suggested a new plan of treatment for certain cases of imperforate anus. Where the bowel could not be readily reached from the perineum the recognized treatment had been, he said, to perform either Littré's operation or colotomy. But in such cases the mortality was very heavy. Mr. Robson advocated making an incision from the central point of the perineum to the coccyx, and then a careful dissection until either the bowel be reached or the peritoneum opened, when the upper end of the rectum or the sigmoid flexure of the colon could be brought down and sutured to the skin in the anal region. Mr. Robson described the case of a child of a day on whom he had performed this operation last March. The child recovered without a bad symptom, and when last seen the anus appeared normal and there was a daily motion. He considered the operation not difficult if a catheter were passed into the bladder and a good horizontal light was available. Mr. Harrison Cripps criticised Mr. Robson's statistics, and said that he had collected a hundred successful cases of Littré's operation. He had himself had five successful cases out of sixteen. Where no sign of

an anus could be found he remarked that the results of operations were much more favorable than when some trace could be seen, as the malformation was often more serious in the latter case. He preferred Verneuil's operation of resection of the coccyx without opening the peritoneum.

We are threatened with another hospital in London in commemoration of the Queen's jubilee. Yet those already existent are languishing for want of funds, and in some the wards have been partially closed. The new institution is to be a special hospital *devoted to all the specialties*, and is to be located in the aristocratic neighborhood of South Kensington. That such a hospital can really be needed no well-informed person can for a moment suppose. To say that it is being started as a commercial speculation in the interests of certain medical men would probably not be far from the truth!

London, January 26, 1887.

On Tuesday last Sir James Paget delivered his inaugural address at the Pathological Society on assuming the presidential chair. He observed that it was characteristic of modern pathology that it offered work sufficient for the employment of nearly every variety and opportunity of the scientific mind. There was in it work not only for the anatomist and physiologist, but for the clinical observer, the experimentalist, the minutest microscopist, the statistician, the chemist, the naturalist, the historian, the psychologist, and yet more. Of all these methods of study, Sir James Paget remarked that there were only two with which he had been much occupied—those of pathological anatomy and of clinical pathology in active practice. We might justly believe, he said, that practice and pathological anatomy, if studied with the scientific mind and methods, would still contribute largely to the progress of the whole science of pathology. We heard science and practice spoken of as in opposition, and sometimes as if they were mutually distrustful. What practice might be depended much more on the person engaged in it than on its own subject-matter. It might be for one a noble profession; for another a vile trade. In equal contrast it might be a mere useful art practised by one who had neither love nor knowledge of any science, or to the man of scientific mind it might be a thoroughly scientific study as well as an applied science. As examples of scientific researches made in active practice were instanced those by which Bright attained the knowledge of the disease bearing his name, and Jenner's discovery of vaccination. As to the latter, we must observe that Jenner was a thorough naturalist, trained by John Hunter. Practice, said Sir James Paget, was full of opportunities for science. He suggested one group, viz., the action of specific medicines, such as that of quinine in malarial diseases, of mercury and of iodide of potassium in syphilis, of arsenic in many cases of psoriasis, or of bromide of potassium in some cases of epilepsy. Here were sure facts, but among these empirical facts modern scientific work in practice might win great riches in pathology. For the medicines he had named were not only remedies, but diagnostic tests, and we might guess that each of them detected the presence of some material belonging only to the disease which it cured. Here, then, was work for the scientific practitioner. He might find the material and more, if he would observe the facts in practice more minutely, and record and collect them, and bring to bear upon them as much light as possible from other sections of pathological science. They would yield more knowledge, and his practice would be promoted to a better title than "empirical."

The fact pointed out by Dr. Bright, that there was a form of dropsy always associated with disease of the kidneys, was accepted at first as a singular fact and nothing more. It would be difficult to tell now into what, with fifty years of scientific culture, that singular fact had grown. Could any fact stand more alone than did that of the use of vaccination as first observed by Jenner? Now it might be honored as the first knowledge attained in all that wide range of knowledge in which Pasteur's great work had been done, and to which Power and Klein had lately annexed their admirable discovery of the true source of the milk scarlatina. There were many more of this group of the facts of which we had better knowledge in practice than we had in morbid anatomy or any other section of pathology. As instances, Sir James Paget referred to predispositions to disease, functional diseases, sequelæ to certain diseases, and hybrid morbid conditions. The best way to remedy these defects was by study and minute scientific work in practice. It could be proved by the example of other sciences that the more minute the inquiries, and the facts obtained by them, the more sure and complete would the fusion of pathology become with the whole body of biological science, and the more would it thence gain. Whenever possible, minute microscopical examinations should be made upon the living as well as on the dead morbid structures. He uttered a warning suggested by the word "structureless." It suggested that we had really reached a boundary, that something was really structureless, or that there was a protoplasm which was the same always and everywhere, at least in the same species. The protoplasm in every structure, he remarked, must be essentially different from that of every other, and these differences would be discovered by our successors if we did not discover them. At the same meeting of the Pathological Society, Dr. Handford showed a specimen of fatty tumor of the heart, and said there was no satisfactory example of a true lipoma of the heart in any of the nineteen principal museums in the kingdom. There were only three doubtful specimens, two of which were probably examples of fatty overloading, and the third was classed among "tumors of doubtful origin."

Dr. Ord showed some fragments of a vesical calculus which had been passed per urethram as the result of spontaneous disintegration. The patient was a gentleman aged seventy-five, who had for six years past had both sugar and albumen in his urine. Large crystals of free uric acid were also passed. The fragments passed consisted of free uric acid and urate of ammonia.

Obstetricians have been greatly interested by a paper read by Dr. Pedley, of Rangoon, at the last meeting of the Obstetrical Society. The subject of the paper was the Burmese and their customs, especially in obstetric matters. Midwives were employed who were of low class and ignorant, and the more decrepit with age they were the more were they respected. As among some other uneducated nations, every method was used to exclude air from the lying-in chamber, in which also a wood fire was lighted and, there being no chimney, the smoke filled the room. Abdominal pressure was employed throughout labor. A silk scarf was also tied tightly round the body above the umbilicus, and drawn tighter as the case proceeded, their idea being that it prevented the uterus from rising into the chest. In all first cases the midwife tore the perineum, either with her thumb-nail, which was grown sharp and long for the purpose, or with her great toe-nail. After delivery of the child, if the placenta did not follow quickly, the cord was dragged on, and, if this failed, the placenta was removed by the hand or torn away piecemeal. The mother was washed, the whole body rubbed with turmeric, and saffron plastered over the vulva. The fire was kept up, and hot bricks wrapped in rags, or bags of hot sand, placed on the abdomen, and twice a day the patient squatted over smouldering embers upon which turmeric had been thrown, or over steam arising from hot bricks. The skin was often blistered, but heat was supposed to heal the parts. When delivery was delayed, various barbarous methods were used, such as standing on the abdomen or placing a bamboo or plank across it, and pressing on each end. These methods were very fatal. Burmese women really needed but little assistance if left to nature, as their pelves were

roomy, and expulsive efforts strong. The Burmah branch of the "Countess of Dufferin's Fund" had determined to undertake the supply of properly trained native midwives.

In Dr. Langdown Down's recent Lettsonian Lectures, he touched on the recent controversy as to the higher education of women, started by Dr. Withers Moore's remarks on the subject in his presidential address at the annual meeting of the British Medical Association at Brighton, in August last. Dr. Down is not one who sees danger in every form of higher education. He said women should be made fit to be not only "mothers of men," but also companions and helpers of men. At the same time he does not approve of over-pressure, and uttered a warning as to the danger of cultivating too much the "emotional side" of woman's nature.

A curious case has been occupying the attention of the law-courts for some days, and was decided yesterday. A gentleman, while dining at a restaurant off some quails and chopped spinach, felt something stick in his throat. This ultimately proved to be a threaded needle, as after passing down and causing an ischio-rectal abscess, it was recovered. A fistula resulted, and two operations were performed. He brought an action against the restaurant keeper, but has been non-suited.

The Wilson bequest is still exciting much interest at the College of Surgeons. No decision has as yet been arrived at.

Dr. Wilks is to be the new President of the Neurological Society.

The following announcement appeared a few days ago in the advertising columns of a daily paper: "A medical practitioner of high standing in the West End of London has received, in the form of a New Year's greeting, the following: 'Asses can be hired or bought.' He begs to say that the Ass that sent it is SOLD."

OUR PARIS LETTER.

THE POSSIBILITY THAT THE SO-CALLED PREVENTIVE TREATMENT FOR HYDROPHOBIA MAY ITSELF ORIGINATE THE DISEASE.

PARIS, January 14, 1887.

PASTEURISM has taken an unlucky turn of late, for certain circumstances have been brought to light which are anything but favorable to the method, and that by men who are not necessarily adversaries to it, but who are earnest investigators, in common with the illustrious biologist who has given his name to the method, for the well-being of humanity. Professor von Frisch, of Vienna, has, after having performed several experiments with the virus of rabies supplied to him by M. Pasteur, come to the following conclusions: "Most of the animals which were submitted to the preventive treatment after subcutaneous inoculation with street rabies, died of the disease even when the period of incubation was thirty-four days. The experiments, according to M. von Frisch, show that M. Pasteur's method of rendering animals refractory to rabies is not yet proved to be quite certain. There is not yet a sufficient scientific basis for the application in man of a preventive treatment after the bite of a rabid animal." But the most appalling reflection suggested by von Frisch, is "the possibility that the preventive treatment, or, at any rate, the intensive method recently adopted by M. Pasteur, may itself transmit the disease." A case lately brought to the notice of the Paris Academy of Medicine by Professor Peter would seem to afford grounds for such a hypothesis. It was that of a young man, aged twenty, who was bitten, about the beginning of November last, by a dog which, recognized by a veterinary surgeon as being mad, was killed. Two days after the patient went to M. Pasteur's laboratory in the Rue Vauquelin, where the inoculations, according to the intensive method formulated by M. Pasteur, were performed in the hypochondriac region. Three inoculations were practised daily for twelve consecutive days, the first having been commenced on November 2d. The patient's health remained perfect to December 12th, when he experienced for the first time a premonitory symptom of considerable importance, viz., pain originating *from the points where the antirabic inoculations had been practised*, and not from the cicatrix of the bite in the finger. His indisposition soon became general and was attended with a feeling of extreme weakness; the patient refused to eat, and he died four days after, that is on December 16th, without having had any convulsions, about six weeks after the bite. Dr. Miquel, who was sent for, arrived just to find the patient dead, with froth at the mouth.

"It is impossible," observed M. Peter, "not to be struck here with at least two facts: The first is, that the premonitory pains set in, not in the bitten finger, but from the points of the inoculations. The second is, that the symptoms were not those of ordinary hydrophobia, for, setting aside some spasms of the œsophagus, the predominant accidents, instead of being of a convulsive character, were paralytic." Dr. Dujardin-Beaumetz did not find Professor Peter's observation conclusive, adding that nothing proved that the patient in question died of rabies; the patient had not been seen by a medical man and no autopsy was made. M. Chauveau, the well-known veterinarian, conceded to M. Peter that the patient may have died from rabies, though this has not been demonstrated. Even were the fact admitted, it would only prove that the preventive inoculations were inefficacious, and nothing more. In fine, it was going too far to assert that Pasteur's method was infallible. As to pretend that the rabies in the above case had been communicated by the inoculations, is quite another matter. The paralytic form of the malady proves absolutely nothing, and as much may be said of the premonitory phenomena which might have had their starting-point at the seat of the inoculations. These local phenomena are often wanting, and they have, in fact, a value of little importance. M. Verneuil finds that M. Peter abuses the *post hoc ergo propter hoc*. When one has been inoculated with an infectious malady and dies, it is not always, and fatally, from that malady, and he regrets that the observation of M. Peter is incomplete, and that it does not present the rigor of a scientific fact. He also wanted to know the reason why the veterinary surgeon had the dog killed that bit the patient, if it was only to ascertain that it was rabid, for he must certainly know that one can learn nothing very serious at the autopsy which would enable one to form a positive diagnosis of rabies, unless he inoculated another animal from the spinal marrow, which was just what he omitted to do.

At the same meeting M. Trélat, the President, read a letter that he had just received from Prince Zughil, of Russia, stating that ten Russian soldiers that had been bitten by a dog were sent to Paris to undergo the inoculations at M. Pasteur's laboratory, adding facetiously that they returned "cured," but that the dog which bit them was at the time, and is now, quite well. This excited some hilarity, but M. Trélat gravely remarked that this letter is interesting in the sense that it attests the innocuity at least of the inoculations, and that it should be saved as a document for the archives of the Academy. The discussion, which promises to be very exciting, was resumed on Tuesday last, but as several members are taking part in it, I shall report the result in my next.

In a report from M. Béclard, Dean of the Paris Faculty of Medicine, it is stated that the number of medical students regularly registered for study during the official year 1885–86 was 3,696, of which 533 were foreigners. Of this last number 108 were women, the greater part being Russians.

Professor Pajot, the well-known accoucheur, having completed his seventieth year, has retired, and his chair is to be temporarily occupied by Dr. Pinard, an agrégé of the Paris Faculty of Medicine.

DANGERS OF ADMINISTRATION OF ETHER IN NEPHRITIS.

To the Editor of The Medical Record.

A recent issue of your journal contains an article by Dr. Henry B. Millard—on "The Dangers of the Administration of Ether in Nephritis and in Bright's Disease." As the author has made some effort to present the literature on the subject, I beg to offer an important contribution.

During the winter of 1865–66, I lost a patient from uræmic poisoning a few hours after closing a laceration of the perineum, and in a subject otherwise in perfect health apparently.

This case drew my attention to the danger attending the administration of ether with any existing disease of the kidneys. It was reported to the Obstetrical Society; other cases have been given from time to time, and published in the different medical journals. Very little has been written on the subject, but I have had credit for the original investigation.

At the annual meeting of the State Medical Society, February, 1872, I read a paper on "Chronic Cystitis in the Female," which was reported in the medical journals of the city, and was afterward published at length in the *American Practitioner* for February, and in the "Transactions of the State Medical Society" for that year. I there state—"To the effects of the anæsthetic I attribute the chief danger attending the operation in the advanced stage of the disease, while from the irritability of the bladder its use is indispensable. As the kidneys are barely able to perform their function sufficiently well to preserve life, the balance is easily lost in the attempt at elimination, and death from uræmia rapidly takes place."

During my service as "Surgeon in Chief" of the Woman's Hospital, it was a standing rule, which I endeavored to enforce, that in every instance the condition of the kidneys should be carefully investigated before the administration of an anæsthetic.

In the first and in the subsequent editions of my work on "The Principles and Practice of Gynæcology," this subject will be found treated of, and in the Index under the head—"Ether, danger of, in cystitis with renal disease."

Thomas Addis Emmet, M.D.

January 31, 1887.

HOSPITALS, THE SICK POOR, AND ALL ENGLAND.

To the Editor of The Medical Record.

Sir: The rapid growth of the population of Great Britain in recent years has caused a corresponding increase in the number and variety of those cases of sickness among the poor which can be adequately treated only in hospitals. Along with the increase of these cases there has been a similar growth in the hospital provision for meeting their necessities. But while the sick abound and the hospitals are numerous, there is often experienced very great difficulty in finding out the right hospital for the right patient at the right time. Hence arises much unnecessary suffering, with loss of time and money, and sometimes even the loss of life itself. These circumstances have, for a long time, forced themselves upon hospital managers; but there has appeared to be no general method applicable to all cases, which would at once and entirely put an end to the difficulties.

The Hospitals Association was formed some years ago, with the view of becoming a central meeting-ground for all hospitals on the one hand, and for all on the other hand who might desire to come into relationship with hospitals, either as patients or in any other capacity. To a considerable extent these objects have been gained, and now, by means of the Association, it is possible to place a given patient in a given hospital with little or no loss of time, and also to obtain any kind of knowledge which may be desired concerning almost every hospital in the United Kingdom, or in the world. The resources of the Association have recently received such a degree of development that the objects which formerly were but partially and incompletely carried out, will, in a short time, be perfectly accomplished, and all these resources will then be placed at the disposal of every member of the Association, and every institution which may be now or hereafter affiliated with it.

It is desired to bring every parish or congregation, and even the remotest villages and hamlets, by affiliation, into immediate and permanent relationship with the hospital system of the United Kingdom, and with the Hospitals Association as the centre of the system. By this means every person needing the peculiar treatment which hospitals alone can give will be enabled to obtain, if eligible, without inconvenience or loss of time, the highest degree of medical and surgical skill which the science of the time affords. If the efforts of the Association be adequately seconded it is hoped to establish by its agency a fully equipped ambulance system for each large centre of population; and, by arrangements made with the various railway companies, to secure the cheap and easy removal to the nearest hospital of persons living in remote and outlying districts. In order to the complete carrying out of these objects the Association has prepared a scheme, which is hereby submitted to the parish clergy and the ministers of congregations, and also to all other persons who may be interested in the care and cure of the sick poor. The scheme is as follows:

I. Each parish, congregation, village, or hamlet, is invited, through its clergyman, minister, or other representative, to affiliate itself to the Hospitals Association by the formation of a "Hospital Society." In either case the annual[1] subscription will be one guinea, and that will secure all the advantages detailed above, together with the weekly publication, *The Hospital*. It is hoped that wherever it is practicable, a "Hospital Society" will be formed, consisting of the clergyman or minister as president, the local doctor or doctors, and two honorary secretaries, one of whom should be a lady. There can be little doubt that the poorer the parish or congregation, the greater would be the advantages derived from affiliation. With the view of bringing these proposals more fully under the attention of those actively interested in the welfare of the sick poor, a congress will be held in May next, under the presidency of Sir Andrew Clark, Bart., M.D., to explain, consider, and finally consolidate the work now begun.

II. The Hospitals Association will be an Immediate Aid Society and its Central Office will be in London. The Secretary will give prompt assistance in the placing of difficult and other cases in those hospitals which may be most suitable for them. Any clergyman or minister of an affiliated congregation having difficult cases for hospital treatment, instead of making applications in all directions, and often fruitlessly, will at once communicate with the Secretary at the Central Office, and his difficulty will be at an end.

III. The office will be a *Bureau of Information* and a *centre of reference*. It will give all possible facilities for gaining the completest knowledge of any and every hospital in the kingdom, and of hospital affairs generally. It will arrange for lectures and illustrations of hospital life for the winter months. It will provide trained and eminent lecturers. It will give aid and advice in the management of public meetings, and co-operate in obtaining men of standing and ability as speakers on specially important occasions.

IV. The new journal of the Association, *The Hospital*, which is published weekly, will be sent post-free every week to each subscribing member of the Association, affiliated parish, or congregation. *The Hospital* will con-

[1] In the case of individuals, a single payment of ten guineas constitutes a Life Member.

tain the latest, most accurate, and most interesting information concerning hospitals and kindred charities, as well as instructive articles on medical and sanitary questions and the related topics.

V. Facilities will be offered whereby members of the Association, and of affiliated societies, may from time to time visit and inspect the general and special hospitals and other institutions of a like kind, thereby obtaining at first hand whatever knowledge of the subject they may wish or require.

Such is the plan which The Hospitals Association commends to clergymen, ministers of religion generally, and to all other persons who are concerned in the well-being of the sick poor. It is conceived in the interests of the poor and of those who have the care of them. It is easy to see, however, that not only will it be of inestimable service to the sick, but also that the hospitals and their work will thus be brought into immediate practical relation with every parish in the kingdom, and will so become known, valued, and supported, as they urgently need and justly deserve.

There can be no question that if the scheme becomes popular, as it is hoped, much unnecessary suffering will be prevented, much waste of time avoided, and much hostile criticism of hospitals, their work and their methods, brought to an end.

Applications for membership, or for further information, should be made to the Secretary, Hospitals Association, Norfolk House, Norfolk Street, Strand, London, W. C. I am, etc., HENRY C. BURDETT.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 30 to February 5, 1887.

BRECHEMIN, LOUIS, Captain and Assistant Surgeon. Granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be spared by his department commander. S. O. 28, A. G. O., February 3, 1887.

POWELL, JUNIUS L., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect when his services can be spared by his department commander. S. O. 24, A. G. O., January 29, 1887.

BURROWS, C. C., First Lieutenant and Assistant Surgeon. Ordered for temporary duty as Post Surgeon at Fort Barrancas, Fla., to take effect upon the expiration of his present leave of absence. S. O. 24, Division of the Atlantic, February 3, 1887.

CLENDENIN, PAUL, First Lieutenant and Assistant Surgeon. Ordered for duty as Post Surgeon at Camp Pena Colorado, Tex. S. O. 14, Department of Texas, January 26, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 5, 1887:

	Cases.	Deaths.
Typhus fever	1	0
Typhoid fever	7	5
Scarlet fever	34	4
Cerebro-spinal meningitis	3	2
Measles	500	78
Diphtheria	100	52
Small-pox	6	6
Yellow fever	0	0

THE TREATMENT OF CHANCROID BY SALICYLIC ACID.—The use of salicylic acid in the therapeutics of soft chancre has been recommended by various authors. Dr. Giuseppe di Bella, in a report of cases treated in the clinics of Drs. Monteforte and Santi-Sirena, says that this agent has acted promptly and efficaciously in a large number of cases. Hebra has seen a number of cases of chancroid cicatrize in a very few days under treatment by salicylic acid. Dr. Ping y Falco has also obtained most satisfactory results with this same agent in similar cases. Dr. A. Farriols Anglada has reported thirty-two cases of soft chancre in which salicylic acid was used with the happiest results (*Journal of Cutaneous and Genito-Urinary Diseases*, February, 1887). This method, he says, possesses many advantages over the others hitherto used, and especially over the abortive plan. It is very simple, and the patient himself can carry it out; it is only necessary to wash the chancroid with some antiseptic fluid, and then to dust it with finely pulverized salicylic acid. In the great majority of cases no more than two applications in the twenty-four hours are required, and in a few days (four or five, according to the author's experience) the ulcer loses entirely its specific characteristics. When this result has been obtained, that is, when the lesion has been converted into a simple ulcer, the applications of salicylic acid should be suspended, and a carbolic-acid lotion or boracic-acid ointment employed. Under this treatment the ulcer becomes covered with healthy granulations, and cicatrization proceeds with great rapidity. Finally, Dr. Anglada urges, if we bear in mind that salicylic acid causes hardly any pain or inconvenience of any sort, in this way differing so greatly from the caustics ordinarily employed, we are forced to admit that it is a most valuable therapeutic agent in the management of soft chancres.

PALATABLE TEREBENE.—The following formula is said to produce a good mixture, and is not unpalatable:

℞. Terebene..... 1 part.
Glycerine,
Spt. vini rect.,
Syr. simpl.....āā 15 parts.

M. Ft. mist. A dessert-spoonful for a dose.

THE COCAINE CRAZE.—In an article entitled "Sensationalism in Therapeutics," Dr. C. H. Hughes (*Weekly Medical Review*) says: "The truth about cocaine is that it is a tonic and stimulating exhilarant of some power in melancholia, mental depression, and nerve-weariness. That it acts rapidly but much more evanescently than morphia. That excessively used it intoxicates and converts melancholia into mania. That, given largely in the upright position, it is capable of inducing vertigo, whether, as Dujardin-Beaumetz thinks, by inducing anæmia is not proven. That as an antidote to alcoholism and its effects it is not equal to morphia. That it is not equal to morphia as a tonic in melancholia, or as a narcotic in certain states of nervous debility. That in equal doses it nauseates more certainly than morphia. That it is not an antidote to meconophaggism, though beneficial if judiciously used and timely abandoned. That it may be used with advantage, if carefully given, in the withdrawal of opium and the cure of the opium habit, as one of many substitutes, but cannot be alone relied upon. That it intoxicates some persons and poisons them. That its continuous use is difficult to break off. That it is probably capable of developing permanent madness, like similar intoxicants, as a few doses occasion temporary insanity. That it is a dangerous therapeutic toy, not to be used as a sensational plaything. That it will probably help to fill rather than deplete the asylums, inebriate and insane, if it should unfortunately come into as general use as the other intoxicants of its class. As an intoxicant it is more dangerous, if continuously given, than alcohol or opium, and more difficult to abandon."

INJURY OF THE EAR CAUSED BY THE BLAST OF A BURSTING SHELL:

WITH SOME REMARKS ON THE EFFECTS OF EXPLOSIVES ON THE ORGAN OF HEARING IN WARFARE.

BY SAMUEL SEXTON, M.D.,

NEW YORK.

THAT the ear may be injured by the violence of aërial impact, or concussive force, propagated by the explosion of gunpowder, has been known ever since the introduction of explosives in military warfare. Owing, however, to the obscurity of traumatic lesions of the drum of the ear, or of its deeper parts, and the limited means of observation at the command of the military surgeon in the field, it has been more difficult to study these injuries than most other wounds. Such was my own experience at least, and reference to the literature of the subject shows that the opportunities of writers on military surgery were probably no greater in this respect. It is a fact, moreover, that from the suffering occasioned by other and more painful wounds simultaneously received, together with the bewilderment caused by nervous shock, aural injuries are liable to be entirely overlooked. Indeed, in some of the cases about to be described there were serious wounds of the ear of which the wounded men themselves had been unconscious up to the time of my examination, several weeks after the accident. It may be stated here, on the contrary, that after artillery engagements it is not unusual for participants to fancy that deafness, due to other causes wholly, has been produced by the loud sounds of great guns, and since the War of the Rebellion applicants for pensions not infrequently present their cases with the statement that aural disability has originated in this manner.

While the writer was recently seeking information from perons having had experience in the field or on shipboard, especially among army and navy officers, an opportunity quite unexpectedly presented itself to investigate thoroughly the effects of concussive force on the ears of a number of men in the midst of whom a twelve-inch mortar shell, weighing five hundred and eighty-five pounds, and containing a bursting charge of twenty-seven pounds of rifle-powder, was accidentally exploded. This took place at the United States Ordnance Proving Ground, Sandy Hook, October 21, 1886, at 3.30 P.M.[1]

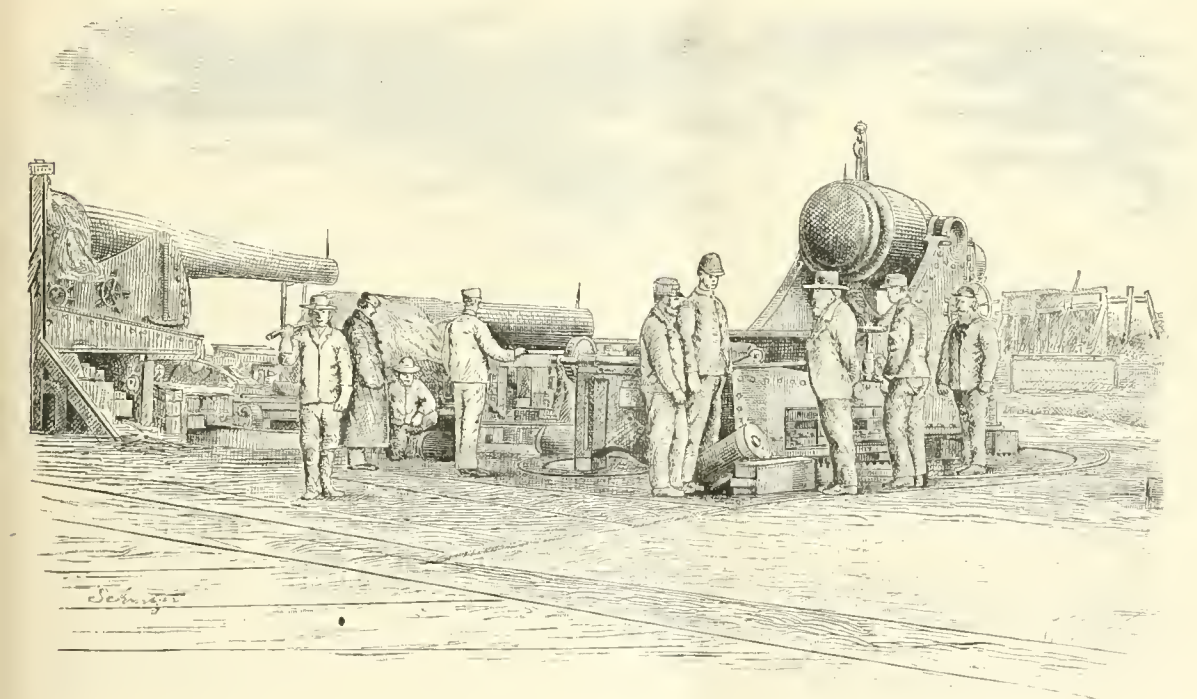

FIG. 1.

The effects produced by the bursting of this shell, both as regards the aërial concussion of the blast and the distribution of fragments of metal, were, of course, similar to those produced by the explosion of projectiles fired from great guns during an engagement; and, it is hoped, since a careful study of wounds of the ear arising from this cause have never been reported, so far as known, that a detailed account of the conditions of the organ of hearing, found to exist in the persons injured, may be of interest to both medical and military men.

The scene of the catastrophe, as shown above, was produced from a photographic view taken on the spot by my friend Mr. Walter C. Tuckerman. The men were taken in about the same position they occupied at the time of the accident; the places of three of them, namely, Lieutenant Medcalfe and private King, killed, and Cor-

[1] The ordnance officers on duty at the time of my visit, namely, Colonel Mordecai, Captain Shaler, and Captain Whipple, kindly offered every facility in aid of my investigation, as did also Colonel Janeway, of the Medical Department, U.S.A., Post Surgeon, Governor's Island.

poral Goodno, absent in hospital, were occupied by other persons.

The diagram of the twelve-inch mortar, gun-carriage, and platform (Fig. 2), where the firing was taking place, was kindly designed by Captain Whipple; the facings of the men are designated by arrows, and it also shows the direction and force of the wind at the time. The shell with a drift and hammer, and thus exploded it) was instantly killed, and his body was blown fifty-five feet away; Lieutenant Medcalfe, who was standing by the side of the shell, was blown twenty-two feet and died in thirty minutes; private Clark was blown fifteen feet. The other six men kept their feet during the explosion. Eight men thus escaped with their lives, but all of them

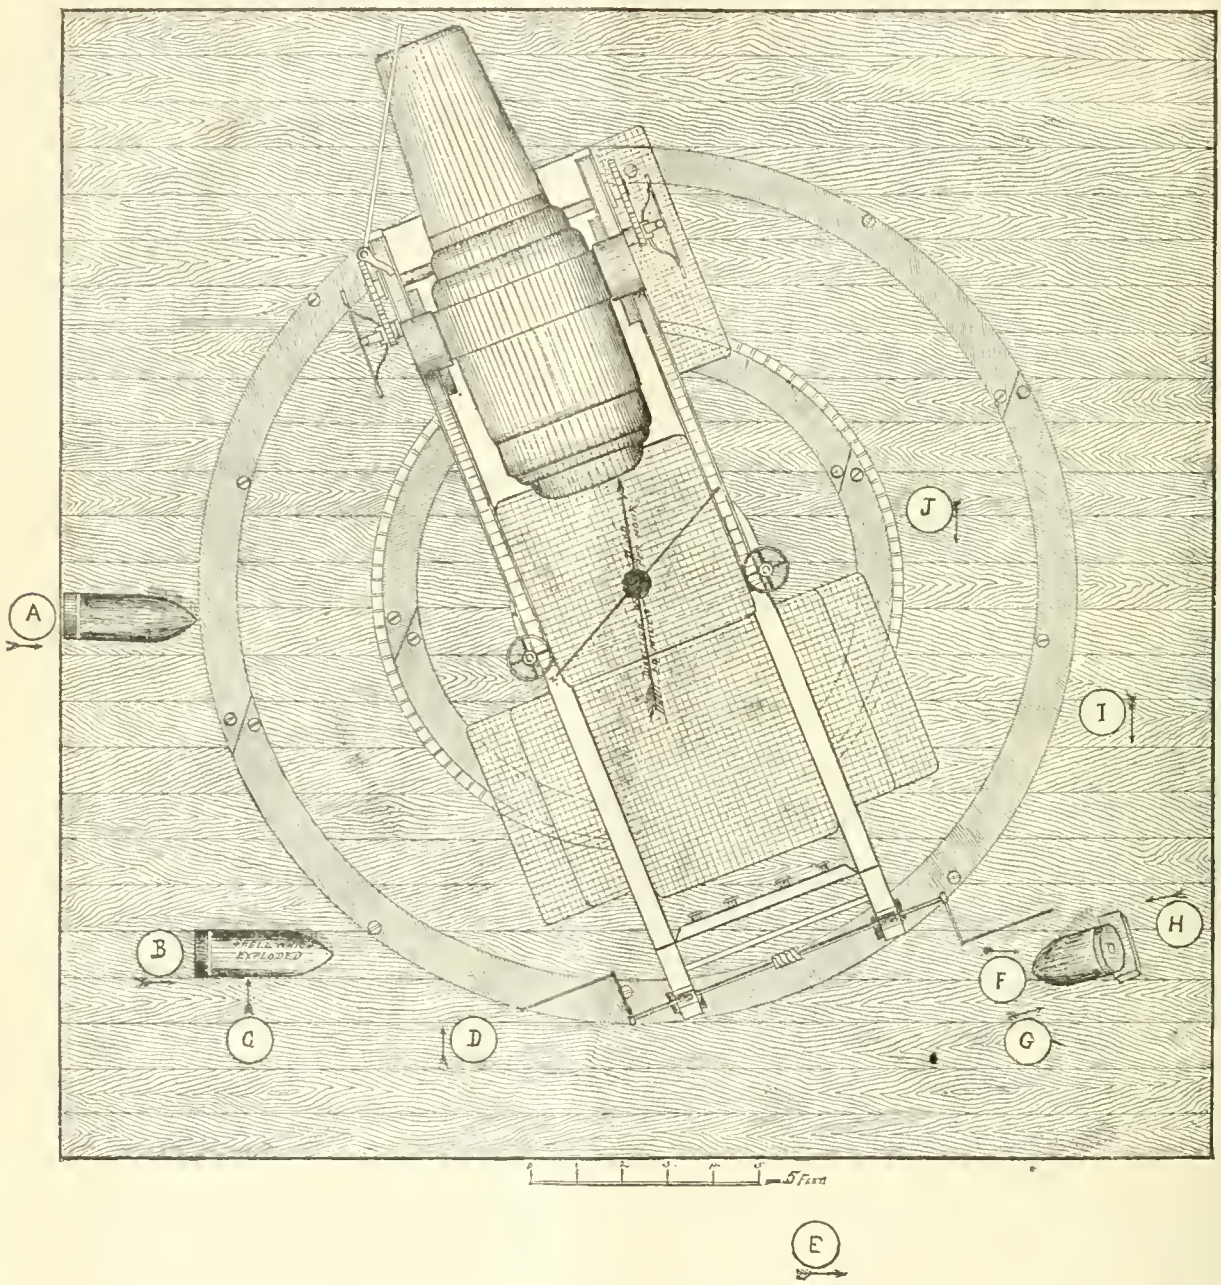

Fig. 2.

distance of the men from the shell which exploded was as given below:

A. Sergeant Abbott,	position	8	feet	from	the	shell.
B. Private King,	"	at the base of the shell.				
C. Lieutenant Medcalfe,	"	at the side of the shell.				
D. Corporal Clark,	"	4	feet	from	the	shell.
E. " Goodno,	"	12	"	"	"	"
F. Private Cunningham,	"	15	"	"	"	"
G. " Cramer,	"	15	"	"	"	"
H. Mr. Sinclair,	"	19	"	"	"	"
I. Private Burns,	"	19	"	"	"	"
J. Corporal Ingram,	"	16	"	"	"	"

As an immediate effect of the explosion, Sergeant Abbott was blown ten feet from his position. Private King (who was closing the screw plug in the base of the

were more or less injured by the concussion, and some of them received contused wounds or were burned by the blast.

The three men first described below were examined at the Post Hospital, Governor's Island, October 31st, where they had been sent for treatment. They were still suffering from shock and contusions, but able to walk without assistance to the office where the examinations were made.

Case I.—Sergeant John Abbott, aged thirty-four, was kneeling on right knee and toe when explosion occurred, presenting right ear toward the shell. He was thrown ten feet by the force of the concussion, found himself upon all fours, but got up immediately and ran some thirty feet before looking to see what had hap-

pened. Noticed that the right side of chest, shoulder, and face were burned by the blast. As regards his hearing, although there was much talking and shouting, he could hear nothing at first. He was much confused, but had no vertigo or pain in the ears. An hour after the accident, however, the deafness was found to be confined to the right ear. After going to bed blood was observed on the pillow, and continued to trickle from the right ear for two or three hours, when it ceased. He slept but little. Pain has been experienced in injured ear on blowing the nose, or swallowing only.

Hearing: Right ear, ordinary voice only; left ear, low voice if plainly spoken—distance, eleven feet.

Examination of ears.—Auricles and canals were healthy; the latter are small.

Right drum-head: A large, irregularly ovoidal perforation of the drum-head exists in the posterior segment; it is bounded anteriorly by the malleus handle, inferiorly by the annulus tendinosus, and above by the membrana flaccida. There is a narrow margin of the membrane between the perforation and posterior wall of the external auditory canal. (This opening was temporarily occupied by a dark crust, probably of inspissated

Fig. 3.—Abbott: Right Drum-head.

muco-sanguinolent matter.) The anterior segment is dull and fleshy-looking (cicatricial?); the membrana flaccida is considerably injected. The short process is just visible, pressing out as a lighter point in the drum-head.

Left drum-head: Slightly atrophic, moist-looking, and opaque. Short process rather prominent, but other landmarks somewhat faint.

Patient has some autophonous phenomena, the voice seems lisping, and for three or four days past there has been tinnitus aurium resembling the sounds heard in a shell when placed to the ear. Vision unaffected.

November 27th.—(Seen at Sandy Hook.) Right ear: The upper portion of the anterior segment is now opaque, slightly vascular, and has a cicatricial appearance; the lower portion is partly cicatricial, exposing some fibrous structure extending perpendicularly. A large, dark, partially inspissated blood-clot yet remains on the lower portion of posterior segment, extending upward in front of the malleus handle; reproduction of the membrane is probably taking place beneath this clot. The clot not shown in diagram. Patient hears low voice at fifteen feet plainly in both ears, but when several persons are conversing he cannot follow them. His voice still sounds to him as if he were lisping. Has occasional tinnitus.

Case II.—George Clark, aged twenty-seven; entered Governor's Island Hospital October 23d. Was standing, when the explosion took place, four feet from the point of the shell, looking at King, and having the left ear toward the missile. He was thrown fifteen feet, but jumped up at once. Was much confused with a "dumb feeling" in the ears; first running away from the scene, and then returning. He staggered to the pump, some three feet distant, and felt better after he had taken some water. He has been, however, unsteady in his gait ever since, and is very nervous and giddy. He was employed in running errands nearly all night. Afterward was too nervous to sleep. He could not sleep on the second night, but on the third night was given bromide of potassium, which has been continued ever since.

Status præsens.—Patient complains of pain through temples, with throbbing sensation. His pulse is weak and irregular. There is a noise in the left ear resembling that of a "steamboat."

Hearing: Right ear, low voice; left ear, only loud voice at eleven feet distance.

Examination of ears.—Right ear: The posterior segment of the drum-head rather opaque and there is at about the centre a slightly injected spot. The anterior segment is fairly brilliant, with good cone of light. A dark line extends along the posterior edge of malleus handle, having the appearance of a light brown crust. This might be taken for a shadow, but for the wrinkled appearance of the membrane about its centre, the folds running principally up and down. Syringing the right ear, which has been tried once, gives rise to unbearable pains in the right eye.

Left ear: There is a large loss of substance of the drum-head, embracing most of the posterior segment be-

Fig. 4.—Clark: Left Drum-head.

low the membrana flaccida, extending inferiorly to the tympanic ring, then curving into the lower portion of anterior segment, and through which the inner wall of the tympanum can be seen. The landmarks afforded by the malleus handle are not visible, but the whole membrana flaccida and the upper portion of the anterior segment of the membrana vibrans has a thickened, macerated, and retracted look. There is a pulsating bubble, affording a light reflex in the anterior-inferior portion of the tympanum, and another posteriorly.

A small amount of blood trickled from left ear the night of the injury; there is now discharge of muco-purulent matter. Pain has been experienced in the left temporo-maxillary space. The ear has been syringed several times daily with a pump-syringe, and the mastoid process was blistered three days ago. For twenty-four hours after the injury mastication was painful. Eructations also gave rise to pain. His own voice is autophonous, and sounds "far off" to him. Patient has become highly neuropathic, and says he has "gone all to pieces." He can scarcely stand to-day, and seems to be getting weaker. Complains also of left eye; says it is "blurred." Both pupils are large, but respond to light. There is twitching at the inner canthus of the left eye, and above the angle of the jaw.

November 21st.—(Patient seen at my office.) He has been on duty at Sandy Hook for past ten days. His left arm and leg feel numb unless he is exercising, and especially at night. He is feeling somewhat stronger. Complains of no vertigo, but of much dull pain in temporal regions, which is increased by the firing of great guns. Cold air causes pains in the ears, especially in the left, and patient thinks that the left auricle is colder than the right. The right ear is, however, healthy. The left ear has healed and the inflammation and discharge have ceased. The perforation remaining is as large as when first seen, and shows no tendency toward closing. The malleus handle is scarcely distinguishable. There is pain, at times, in the ear but no tinnitus. He has still, however, tinnitus, resembling escaping steam, in the right ear. Introduction of a speculum into the left ear causes tears to flow from left eye, which also feels irritated. When patient uses his eyes in reading, etc., the left gets "blurred," he says, and "weak."

Hearing: Left ear, loud voice only[1]; right ear, low voice, at eleven feet distance.

Patient becomes confused when several persons are conversing.

November 27th.—(Seen at Sandy Hook.) Patient is now improving and feels stronger. He is less nervous also. In left ear the parts are clearing up, but the perforation is unchanged.'

[1] Captain Whipple writes, December 22, 1886; "I am sorry to say that I hear Corporal Clark, whom I had transferred back to Springfield, is not doing well. His 'hearing' is getting worse, and he seems to have lost his grip." Subsequently, however, Clark again became much better.

CASE III.—Corporal Walter Goodno, aged thirty-four, had just picked up a handspike and walked away from the shell. Thought a keg of powder on his right had exploded and tried to get away. His ankle was hit, hat torn to pieces, and he received a contused wound of the scalp, just below the occipital protuberance. Patient had his left ear turned nearly toward the shell at the time of its explosion. He had autophonia at once, could hardly hear his own voice; but could distinguish pretty well what others were saying, in the right ear. Immediately after the injury there was a great ringing in the left ear. Patient says he felt something (which he fancies was blood) drop down "into the throat from the head" about an hour afterward.

Examination of ears.—Left ear: At the inner end of the canal the cutis is dry, white, and exfoliating, being

FIG. 5.—Goodno: Left Drum-head.

covered with a light coating of boracic acid and iodoform in powder. Almost the entire portion of the drum-head, constituting the membrana vibrans, appears more or less disorganized; the posterior portion is missing, leaving a ragged edge, and the anterior portion has a bruised, fleshy look. The malleus handle is very prominent.

Right ear: Membrana tympani lustreless, uneven, and depressed. Slight injection along malleus handle. A

FIG. 6.—Goodno: Right Drum-head.

large circular area, occupying almost the entire upper portion of the posterior segment, is of recent cicatricial formation, with uneven, depressed, and lustreless surface. Behind this can be seen the inferior portion of the long process of the incus. On the umbo is a small, dark blood-clot. Two parallel folds of the membrane, resembling cords, run from the umbo forward and downward to the margin of the drum-head. The area between these is occupied by disorganized substance. Both external auditory canals are large.

Hearing: Right ear, low voice, if plain; left ear, ordinary voice, if plain, at twelve feet distance. Patient still has autophonia. The pulse is feeble and rather frequent.

December 6th.—(Seen at my office.) Patient has recovered and will report for duty. *The right ear* shows a minute, dark, and depressed cicatrix at umbo. Below this, occupying nearly the entire area of the lower segment of the drum-head, is a large, circular perforation, where there was broken-down tissue before. No inflammatory symptoms remain, and the drum is cured. In the left ear nearly all of the drum-head is absent, and the denuded malleus handle hangs down in front of the inner wall of the tympanum *in situ*.[1] The anterior edge of the round window and the incudo-stapedial joint is exposed to view. All the parts have a whitish, dry appearance. All discharge from the ears has ceased. Syringing or probing the left ear causes a sensitive impression in the left eye and lower part of larynx.

Hearing: Left ear, ordinary voice; right ear, lowest voice, at fifteen feet distance. Watch heard in left ear only on contact; in right, at thirty-three inches. The extent of sloughing in the membranes in this case is remarkable. The great amount of hearing for the voice is also notable, and quite in contrast to the poor hearing-power for the watch.[2]

[1] The diagrams of the drum-heads in this case, as in the others, represent the appearance of the parts when last seen.

[2] Corporal Goodno suffered a relapse in respect to the wound at occiput, which had healed but slowly, and on return to the hospital a small fragment of shell was removed from the wound. After this recovery was rapid.

The following persons were examined at Sandy Hook, November 27, 1886, over five weeks after the accident:

CASE IV.—Mr. Allan G. Sinclair, machinist, aged sixty-two years; has been in the employment of the United States Government for some thirty-seven years, twenty-four of which have been passed in the Ordnance Department. He has been testing guns for twenty years, but has never experienced unpleasant sensations or injury of the ears from this occupation. At the time of the explosion the patient was standing about nineteen feet from the point of the shell, and facing it. At first he was dazed for some moments, but does not think he was thrown down. His hat was blown off. He had no pain in the ears, but a noise in both resembling escaping steam. This still continues, but is less severe. Of late he has felt pulsations in the ears, mostly in the left. These are variable, scarcely ever occurring before about 3 o'clock, A.M., when he fancies they wake him up. His ears have felt "dumb" from the first, at times, and his own voice is autophonous, and seems distant to him. No vertigo.

Hearing: Left ear, ordinary voice only, at ten feet; not so well in the right.

Examination of ears.—Right ear: The malleus handle

FIG. 7.—Sinclair: Right Drum-head.

has a light-brown appearance, and behind it lie some inspissated blood-crusts. A cicatricial area extends from the anterior superior border of the tympanic ring downward, and terminates in a transverse band of thicker tissue below. Underneath this band there is a large loss of substance in the membrane, and under this, below the umbo, extending into the lower portion of the posterior segment, is another area of cicatricial tissue, due to reproductive growth. The denuded short process marks the termination, posteriorly, of the band above mentioned.

A small crust, consisting of epithelium and inspissated blood, which has worked off from the wound of the drum-head, lies on the posterior wall of canal. The parts have healed up entirely, and are free of any injection. Through the large perforation the inner wall of the tympanum is visible.

Left ear: A blood-clot occupies most of the posterior segment of the drum-head, which is elsewhere fairly brilliant. At the junction of the inner end of canal and posterior edge of the membrane, and behind the clot, there is a small ulcerous surface covered with a rather loosely attached scab, the seat of a perforation probably. Both of the external auditory canals and drum-heads are large, and this may account for the great amount of injury. The ears have received no treatment. The very considerable deafness in this case is permanent, rendering general conversation impossible.

December 13th.—(Seen at my office.) Right ear: The crust of epithelium and inspissated blood, which was described as working off the drum-head on to the posterior wall of canal, can be picked off. The small blood-clot behind the short process has become detached, leaving a reproduced dermic layer beneath. The perforation has become smaller, and its circumference looks as if it would contract still further.

Left ear: Membrana tympani cleared up entirely. The crust on the drum-head near the wall of canal has worked off on the canal and can be easily removed. The blood-clot which occupied almost the entire posterior segment of the drum-head is loose, and can be easily removed with the forceps. Beneath this crust, doubtless the seat of a perforation, the membrane has healed up entirely.

Hearing: Left ear, low voice; right ear, loud voice, at fifteen feet distance. Watch pressed against the ears not heard at all. Patient hears the noises in the streets of wagons, etc., like a low, rumbling, unaccustomed

sound. He has no nausea, vertigo, etc., and feels very healthy and strong.

Case V.—Private Michael D. Burns, twenty-four years of age, was standing about eighteen feet away, and was dumfounded by the explosion, felt stunned and dizzy, and had "buzzing" noise in both ears.

Examination of ears.—Both canals are of medium size.

Right ear: There is a marked vascular condition about the superior portion of the drum-head, and extending down along the malleus handle. The drum-head has a general humid appearance, and there is a beginning opacity just in front of the umbo. There is a small cicatrix, with some fibrous lines, in lower portion of posterior segment. Since this ear was more exposed than the left, the abnormalities seen point to extensive injury followed by almost complete restoration.

Left ear: The drum-head has a somewhat humid appearance, due to catarrhal inflammation of the middle

Fig. 8.—Burns: Left Drum-head.

ear. There was a little pre-existing hardness of hearing. There is a recent perforation in the posterior segment near the edge of drum-head. This is partly concealed by a crust, and gives, on inflation, a whistling sound.

Hearing: Right ear, ordinary voice; left ear, lowest voice, at fifteen feet distance. Watch heard at $\frac{5}{33}$ inches in the right ear, and at $\frac{2}{33}$ inches in the left. This man had both auricles frozen two years ago, while out on the plains.

Case VI.—Private Joseph Cunningham, twenty-three years of age, very tall (over six feet) and slender. After the accident patient did not take cognizance of anything for a few minutes, and was dizzy for two days afterward. Has been troubled in both ears since the explosion, especially in the right, which was constantly painful for over a week, and is occasionally so now. He experienced tinnitus aurium, which has not entirely ceased yet. His voice was autophonous and sounded hoarse and unnatural to him in both ears for four days.

Examination of ears.—Right ear: The drum-head is imperfectly developed; it is transparent (as in cases of cicatricial reproduction) and lacks brilliancy. The short process protrudes unduly. *There is a crust on the margin of the posterior segment*, and a slight opacity below the umbo.

Left ear: The same general appearances of the drum-head are present as in the right ear. The outlines of the malleus, however, are much more prominent. The long process of the incus and its attachment to the stapes is very plainly seen through the drum-head. Just posteriorly to the short process a small area of the membrane is much thinner than elsewhere and seems sunken. Notwithstanding these abnormalities the patient gives no history of previous ear trouble, and there is a strong probability that the appearance is due to reproduction succeeding to almost complete destruction of both drum-heads from the explosion. He has a very high palatal arch, and the incisors above and below are "pegged."

Hearing: Right ear, low voice, with difficulty; left ear, lowest voice, at fifteen feet distance.

Case VII.—Private Thomas Cramer, aged thirty-nine, was standing with back toward shell, but the right ear was a little more exposed than the left; felt a stinging sensation from the concussion "all the way up the left side from the foot to the ear." Has felt nothing since. The ears were apparently uninjured. It is difficult to account for the escape of the ears from injury in this case.

Hearing: At fifteen feet distance, lowest voice in both ears, but best in right.

Case VIII.—Corporal Ingram, thirty-two years of age, felt stunned for a minute or so, but had no pain or vertigo; in fact, had no aural symptoms whatever. Patient had accumulation of wax syringed from both ears in 1883. Dr. C. J. Colles examined this man for me, and found that both ears contained considerable soft cerumen. As no symptoms of injury to the hearing organs had appeared, it was thought probable that the presence of this accumulation of cerumen had been the means of

Fig. 9.—Ingram's Left Drum-head.

protecting the drum-heads from the injurious effects of the explosion. This, however, does not appear to have been the case. The patient was seen at my office on December 13th, when the wax was removed. It was found that the quantity of this was not sufficient to occlude the canals. The right and most exposed drum-head looked well; it was probably protected from the concussion by the heavy wooden structure upon which the mortar was mounted. Behind the wax, however, in the left ear, which was turned from the shell, was a quantity of inspissated purulent matter and epithelium. When this was removed the drum-head was found to be red and angry-looking, and the landmarks were not seen. Syringing produced a feeling of faintness and nausea.

Hearing: Left ear, ordinary voice only; right ear, low voice at fifteen feet distance.

December 4th.—(Seen at my office.) There has been no discharge from the left ear, and parts have cleared up slightly, showing great arrest of development, the short process and posterior fold being very prominent; otherwise the landmarks are hardly distinguishable. The entire membrana vibrans is, apparently, in a necrotic state, indistinguishable from the inner wall of the tympanum. A very thick desquamative collection lies at the site of the anterior inferior segment.

December 21st.—(Seen at my office.) There has been no discharge or pain, and the parts are dry. It can be seen that the entire membrana vibrans has been destroyed, excepting a thin edge remaining attached to the posterior wall of the tympanum. Ingram thinks hearing in the left ear has improved. He has no tinnitus, vertigo, or nausea.

Hearing: Left ear, low voice at fifteen feet distance; as tested by König's rods, fifty thousand vibrations per second perceived in both ears.

The diagrams of the drum-heads injured were drawn by Dr. C. J. Colles. The dark shading marks the extent of loss of substance in each case; the lighter indicates the presence of cicatricial tissue. In the case of Cunningham no diagram is given, since the parts were probably almost entirely reproduced.

Remarks.—As might have been expected, the immediate effect of the severe concussion caused by the blast of the explosion just described was dumfounding in the extreme, so far as most of the persons in the immediate vicinity were concerned. The mental confusion which ensued in some of the cases lasted a long time, and in one instance, that of Corporal Clark, it is doubtful if complete recovery ever takes place.

In some of the cases the absence of prominent symptoms of injury of the ear, such as pain in the organ, tinnitus, deafness, or discharge, was noticeable. Soldiers are, however, as a rule, accustomed to endure hardship without complaint, and, in fact, all insensitive persons are liable to overlook ear disease until incapacitated to perform their work. It was only after persistent inquiries were made that some of these persons would admit that they had suffered any injury of the ear.

I have endeavored to obtain some reliable statistics in regard to the frequency of injuries to the organ of hear-

ing during the late War of the Rebellion, but without satisfactory results; thus the number reported by the census-takers in 1880, as furnished me by Mr. Fred. A. Wines, of the Census Bureau, was only fifteen from all causes. These are given below. The meagreness of facts obtained in this manner illustrates the inefficiency of such a method for collecting valuable information. A single shell explosion has, in many instances, doubtlessly, injured as great a number.

ASSIGNED CAUSES OF DEAFNESS—WAR.

Connecticut, "discharge of cannon"	1
Georgia, "firing cannon in war"	1
Indiana, "cannon fired"	1
Illinois, "gunshot wound"	1
Massachusetts, "discharge of cannon"	1

Ohio, "discharge of cannon"	1
Ohio, "severing of tongue cords by shot"	1
Pennsylvania, "shot of gun"	1
Texas, "gunshot wound"	1
Texas, "gun fired close to ear"	1
Wisconsin, "firing cannon"	1
Total	15

The Pension Office, doubtless, might furnish more reliable statistics were the disabilities for which pensions were granted tabulated; but Congress has, as I am informed by Medical Examiner Wood, omitted to make any appropriation for such work. It is to be regretted that more attention has not been given to this matter, since there must be a large number of persons who have suffered injury to the ears from the concussion of explosives, who are as much entitled to be pensioned by the Government from this cause, as from others which happen to be more easily diagnosed.

I have obtained some facts in conversing with officers who served during the War of the Rebellion, which may be of interest here. Commander Robeson, at the naval attack on Fort Fisher, found that the continued explosion of fifteen-inch shell at close quarters gave rise to very disagreeable ringing in the ears, which finally benumbed the hearing sense so much that he could not hear an order given on deck for several days; the disability, however, was but temporary. My friend Dr. Delavan Bloodgood, Medical Director, U.S.N., informed me of a case where deafness was said to be "from concussion of the cannon" in an action on Lake Champlain, July 3, 1813. The case was that of Captain Sawyer, U.S.N., who was a midshipman on board the sloop Eagle, which was sunk by the British flotilla, aided by troops on the shore. The engagement lasted four hours; and the captain was afterward taken to Halifax and confined on board a prison-ship over seven months. It is probable that exposure subsequent to the action very much increased what might have been but a temporary difficulty. On the cessation of the retaliatory hostage system he was immediately ordered to the Constitution, and afterward served in the Brazilian, Pacific, West Indian, and Mediterranean squadrons, and was finally surveyed and condemned, on account of deafness, in 1822.

I am in receipt of a communication from Medical Director Henry O. Mayo (retired), U.S.N., giving his own experience as to the effect on the ear of the concussion of great guns, which is of much interest, since it shows the effect of repeated injuries. He says: "I first felt the effects of concussion from big guns in the summer of 1861, on board the frigate Savannah, while engaged in a scrimmage with some rebel gunboats at the mouth of the James River. As the affair promised to be of a bloodless character, from the respectful distance kept by the enemy, I seated myself in the bridle-port, on the gun-deck, to watch the performance. My hearing was quite impaired for a day or two, but in a short time the effects of concussion passed off entirely.

"Just at the close of 1864 I was attached to the U.S.S Powhattan, of Admiral Porter's fleet, and was engaged five days (three at one time and two at another) in the bombardment of Fort Fisher, and the other batteries at the entrance to Wilmington. Having occasion to go on deck at times during the action, I could only do so by the cabin companion-way, which was but a few feet from the eleven-inch pivot gun. This chanced to be discharged two or three times, just as my head was about on a level with it, going up or down the hatch, and the concussion was tremendous. Once I thought the gun had burst, and taken my head along with it! Upon reaching home, a month or two afterward, I found the hearing of the left ear much impaired, but the right still served me so well that I was enabled to continue my ordinary duties on the active list.

"In the early part of 1870 I went to China as surgeon of the Asiatic fleet. During this cruise I was exposed for one entire day to the concussion of big guns engaged at target-firing on board the flagship Colorado. This gave the *coup de grace* to the hearing of the left ear, and still further impaired that of the right. In 1875 I was retired on account of deafness."

Dr. Mayo is of the belief that the cause of the defectiveness lies in the transmitting mechanism of the middle ear, and not in the inner ear or auditory nerve-tract. *The Eustachian tube of the left* (worst) *ear has always seemed abnormally pervious, while the right was considerably obstructed.* He cannot hear the loudest-ticking watch pressed against the left ear, and only faintly in the right. He can converse pretty well with *one* person at close range, who speaks slowly and distinctly.

It would seem, in cases where chronic catarrh of the middle ear already existed, difficult to determine the exact amount of injury due to this cause and to concussion, respectively. I think that where rigidity or fixation of the transmitting mechanism existed from catarrh the ear would thus be made more sensitive to concussion. *Per contra*, it is found that boiler-makers, who appear to have their catarrhal deafness increased by the terrific concussion from riveting boilers, do not usually complain of hyperæsthesia or of painful sensations therefrom. But this is, perhaps, a question of sensitiveness to such impressions.

Among other instances coming to my knowledge the following are of interest: General Leonidas Polk, a few days after the battle of Belmont, was standing at the breech of an eight-inch rifled gun, which, on being fired, exploded and set off a magazine of fixed ammunition immediately underneath the piece. The captain of the battery and four or five others, who were standing near, were killed. General Polk was very miserable for a few moments from the shock, and was confined to his bed for some ten days. The left ear began to discharge the day of the injury, and continued to run until he was killed, two and a half years later. He had no previous aural trouble, and the deafness following the injury was the cause of much worry.

General Imboden, in an article in *The Century Magazine* for May, 1885, states that at the battle of Manassas he squatted under the muzzle of a smooth-bore six-pounder brass cannon, when it was fired off; the concussion, he says, threw him twenty feet away, causing momentary unconsciousness. There was a gush of blood from the left ear, which has been deaf ever since.

Another case is as follows: David McConnell, late a private soldier in the one hundred and thirty-second N.Y.V., came to the New York Ear Dispensary, November 14, 1879, at which time he was an inmate of the Soldiers' Home, 205 West Thirty-ninth Street. He stated that in 1864 he was engaged fixing shells (torpedoes?) to be used in blowing up some works, when one of them was accidentally exploded. Fragments of the shell wounded him about the left side of the head, one piece striking the ear. He was blown a considerable distance by the blast. He was sent to a

hospital, where the ear ran a good deal, and there have been acute and painful exacerbations now and then ever since.

On examination at the infirmary I found a perforation in the drum-head, and chronic purulent inflammation of the middle ear. The hearing was considerably diminished. He afterward applied for a pension.

The following case came to the New York Ear Infirmary, July 17, 1877, also an applicant for pension. This patient, Bernard Cunningham, stated that he never had any aural affection until after the battle of Gettysburg. He was a private in Company G, Eightieth N.Y.V., and states that on July 1 (1863), a shell exploded near his left ear, from the stunning effects of which he did not recover for a quarter of an hour. On the third day a thin muco-purulent discharge was noticed coming from the left ear; it soon assumed a purulent and offensive character. Patient states that an aural injury was diagnosed by Regimental Surgeon Laughan soon after the injury was received.

When the patient came to me, fourteen years had elapsed since the accident, during which time he had never been free of distressing tinnitus, which was compared to the constant escape of steam under high pressure, with interruptions synchronous with the heart's pulsation. Autophonous phenomena were experienced, and he felt that unless some relief was obtained he should become insane. The deafness was variable—at times very great; usually he could hear a loud voice only in the left ear.

Examination showed the external auditory canal to be greater in calibre than the average, and the drum-head, which was correspondingly large, had a circular perforation in the posterior-inferior quadrant about three millimetres in diameter. In the certificate of disability given this soldier, it was stated that the opening in the drum-head would probably never close, and since there would be a tendency to frequent exacerbations, on account of the exposure to which an out-door laborer is subject, the discharge and autophony, though temporarily alleviated by treatment, would probably never cease altogether.[1]

Injuries like the above are especially important in consequence of affording a basis for claims on the Government for pensions.

In general it may be said that the concussion of great guns is much less in the rear of the piece than just over or at one side, and that the more in advance the greater the exposure to the blast. On shipboard a gun's crew is usually stationed from four to eight feet to the rear of the muzzle, and when protected by bulwarks and decks experience no special inconvenience; but if the ear happens to be on the same plane as the face of the muzzle, the effect at a distance of a few feet is disagreeable or even painful, and causes temporary deafness similar to long-continued concussion previously referred to.

The force of impact upon the drum-head will depend somewhat on the size and curvature of the external auditory canal and the rigidity of its cartilaginous walls; of course the more straight and large the passage, the greater the injury.

The size and tensile strength of the drum-head must be taken into account; if large and brittle, from trophic changes, it is much more easily ruptured.

The facing of the person exposed must also be considered — usually the ear directed toward the object from which the concussive force is propagated suffers most—but in the case of Ingram it was otherwise, the sound-waves having been reflected.

The immediate effect of the blast-impact in the cases injured by the shell explosion at Sandy Hook was undoubtedly upon the exterior surface of the drum-head mainly. While it is true that atmospheric tension is almost equal on both sides of the drum-head, yet a current of air passes much faster along the comparatively large tube comprising the external auditory canal than along up the small Eustachian tube, and hence in most of these cases the drum-head was driven in and contused against the inner wall of the tympanum and retained air with great force. The effect of such violent concussion is to cause the death of the membrane.

The momentum of sound-waves may ordinarily be estimated by the application of the law of central forces—the force being inversely to the square of the distance; the effects, practically, of such intense concussive force, however, cannot be measured by rules governing sound ordinarily, since it has been found by experience that instead of finding himself surrounded near the breech of the gun by highly rarified air, the experimenter may be subjected to quite an opposite condition, namely, one of condensation. In the former, intra-tympanic air would rush outwardly, carrying the drum-head before it. In confirmation of this allegation the puzzling experience related to me by Captain Shaler may be cited: The window-glass of the officers' quarters at the testing-grounds at Sandy Hook, situated some three to five hundred feet to the westward of the gun-park shown in the picture, are liable to be shattered by the concussion of large pieces in practice, and it has been found that *the glass is forced outward at one time and inward at another.* Regarding the drum-heads as window-glass under like conditions, we might find them ruptured by compression from without in one instance, and by distention of intratympanic air in another.

All of us are aware of the difficulty of ascertaining the source of sound in a sea-fog, where vapor-tension varies in a much greater degree than inland. Professor Henry described the reflections of sound which here take place as "acoustic shadows," a picturesque comparison recognizable by everyone familiar with those similar phenomena, namely, the reverberatory detonations of thunder during a storm, where clouds or mountain peaks intervene. It is to the unrecognizable vapor-"peaks" that many unexplained and puzzling acoustic manifestations are due. In the case of Corporal Ingram, cited, the wave from the blast did not nearly so much affect the right ear, which was turned toward the shell, as the left one, the sound having been apparently deflected from its course by the heavy gun-carriage intervening. General Franklin, in describing the battle of Gaines' Mill, in *The Century Magazine*, July, 1885, says it was not heard a mile and a half away; he thinks the dense woods intervening prevented the passage of sound. *Per contra*, the writer recollects hearing the cannonading at the battle of Manassas distinctly, though he was with troops more than one hundred miles distant.

Experiments are wanting to determine the windage[1] of balls. This must depend on their size and velocity, nearness of passage, and the force and direction of the wind. There seems to be no doubt but that the windage of a cannon-ball might rupture the drum-head of the ear. The compression of the air before and around the ball, I am informed by my friend Professor A. M. Mayer, is considerable, and the *velocity* of the compression is equal to that of the ball, which velocity may even exceed that of wind itself. So, an *aërial blow* of such a mass of air, at such high velocity, is probably quite sufficient to rupture the drum-head.

The size and force of modern military explosives having been greatly increased of late years, much more injury to the ear is likely to occur in future than has been recorded of the past, though the number of accidents from premature discharge or from exposure to the blast in firing breech-loading pieces must be less than when muzzle-loaders were in vogue.

[1] The Commissioner of Pensions, the Hon. John C. Black, informs me, in a letter dated February 7, 1887, that Cunningham is now a pensioner "at the rate of two (2) dollars per month for disease, and deafness of the ear."

[1] "Windage," it should be said, is a technical term used in military parlance to indicate the difference in diameter between the bore of a gun and its projectile. The word has been, perhaps improperly, adopted by writers on military surgery, in which sense it refers to the impact of the condensed air surrounding a missile passing near any part of the body.

The extent of the injury of the drum of the ear in each one of the cases reported was dependent on the distance from the shell, the facings at the moment of explosion, and the size of the external auditory canal. In some instances, as, for example, in the cases of Abbott, Clark, Goodno, Ingram, and Sinclair, the drum-heads were driven in with such force as to cause their complete destruction by death of the tissues. In some of the cases, it will be observed that partial or entire reproduction of the drum-head took place. The spontaneous cure, in most of these cases, without leaving any discharge, affords a valuable suggestion in the treatment of inflammation of the ear, as well as in operations on the organ, in healthy persons. It is believed, notwithstanding the great destruction of the membrana tympani, that the chain of ossicles has been left in every case. It is fortunate for man that great augmentation of tension, exerted either from without or from within, upon the transmitting mechanism of the ear, may be experienced without serious injury to the stapes or labyrinth.

Hearing tests employed.—The voice was employed as a test in all cases, its perception being practically the most important function of the ear of a soldier. Whereever the watch was employed, the result is noted in the history. König's rods were employed in one or more cases.

It is the experience of many officers that the vibrations of great intensity which are given off from some field-pieces and bursting shells, charged with high explosives, are more disagreeable than the heavier sounds of great guns. The metal itself vibrates under these circumstances similarly to a tuning-fork.

A very disagreeable jar is imparted to the temporo-maxillary articulation when the individual is near a great gun being fired off. This is lessened, it is believed, by standing on the toes and leaning forward. Some simple precaution, to be employed by officers and men during artillery practice, would seem very much needed, since aural shock is not only painful and distressing, but orders cannot be well heard while the confusion lasts.

There is probably no better protection than a firm wad of cotton-wool well advanced into the external auditory canal. In suggesting this protection it is believed that harm can seldom take place from pressure of air from within, since it is known that the violent introduction of air into the tympanum from the throat, by means of Politzer's method of inflation, seldom ruptures the drum-head, though, if such a volume of air were suddenly driven into the external auditory canal, the drum-head would in nearly all cases be ruptured.

The writer, in finishing this account of the aural injuries done by the explosion, would request that other observers having experience in this direction kindly communicate with him. Any knowledge that may thus be contributed would be of service to military surgeons, otologists, and others.

12 West Thirty-Fifth Street.

Acute Pneumonia in Utero.—A correspondent writes in the *Lancet* of November 6, 1886, as follows: "A patient, U. M——, was admitted to hospital suffering from acute pneumonia (whole of left lung), and a history of illness covering the four days previous to admission. She was eight months pregnant. On the evening of the day of admission her temperature was 103.6° F., and she was delivered of a female infant. The infant died in less than twenty-four hours after birth, with symptoms of acute pneumonia. A post-mortem examination showed acute pneumonic consolidation of the whole of the left lung. The mother made a rapid and good recovery. While there is ample evidence that the other acute specific diseases (so-called 'fevers') are capable of being transmitted by the pregnant woman to her offspring yet *in utero*, this is the first time I have had any evidence that 'acute pneumonic fever' could also be so transmitted."

CONGENITAL HÆMOPHILIA, WITH THE HISTORY OF A REMARKABLE CASE.[1]

By EDMUND C. WENDT, M.D.,

CURATOR AND PATHOLOGIST OF THE ST. FRANCIS HOSPITAL, AND OF THE NEW YORK INFANT ASYLUM.

For the history of this case the writer is indebted to Dr. Kate Parker, House-Physician of the New York Infant Asylum. The case occurred in the service of Dr. George B. Fowler.

Howard B—— was born at 4 A.M., November 30, 1886. His mother was a remarkably well-developed mulatto woman in perfect health. Special inquiry failed to elicit any history of syphilis, nor did a careful and searching examination give the slightest evidence of the disease, past or present. The mother's family was stated to enjoy perfect health. No cases of hemorrhage were known to have occurred in any of its members. Regarding the father, no other facts could be learned than that he was apparently in excellent health.

The mother was twenty-five years of age and a primipara. Pregnancy had progressed undisturbed to full term. The delivery was a very easy and natural process The first stage of labor lasted just six hours and ten minutes. The duration of the second stage was only ten minutes, and birth was almost precipitate. It was a vertex presentation, with right occipito-anterior position. The weight of the child at birth was nine pounds and eight ounces. The infant's appearance would have been quite normal, except for a swelling above and in front of the right ear, with purplish discoloration of the integument. Nothing unusual occurred until 7 A.M. on the following day. At that time there was a severe hemorrhage from the umbilicus, which was apparently checked, however, by the usual treatment. Two slight attacks of epistaxis followed, and some blood was also rejected by vomiting. At 11 P.M. oozing from the navel was again noticed. Although the blood seemed to come from several points, the oozing was most marked at the line of separation from the integument. In spite of all efforts to control it the bleeding continued, with but slight intermissions, until the death of the infant, on the following day, December 2d, at 4 P.M. Before death a few purpura-like spots had made their appearance on the skin of the trunk and extremities. The tumefaction above the ear had perceptibly increased in volume. Death was evidently due to exhaustion from loss of blood. The weight of the child after death was found to have become reduced to eight pounds and nine ounces.

To complete this rather brief clinical record, it should be added that there was no post-partum hemorrhage, that the mother passed through an absolutely normal childbed, and that the placenta was healthy, at least so far as gross appearances were concerned. A microscopical examination was not made.

At the autopsy, which was performed twenty-two hours after death, the following observations were made: The body of the mulatto infant appeared plump and well nourished. Cadaveric rigidity was well marked. No petechiæ or ecchymoses were visible on the integument. The right post-aural region was occupied by a doughy tumor, over which the skin was colored purplish blue.

A hard, shrunken mass, to which adhered crusts of coagulated blood, represented the soft part of the umbilical cord. At the line of junction with the integument a few small and superficial erosions could barely be made out. The umbilical vessels were carefully prepared, and, on opening the abdomen, traced into the liver and through the hypogastric arteries into the iliacs. They were patent on section, and presented no abnormality whatsoever. They contained no blood.

When the abdominal cavity was opened about two tablespoonfuls of fluid blood were collected from its different compartments. The blood was thinner, but not lighter-colored than normal. Not a single clot was

[1] Read before the Manhattan Medical and Surgical Society, January 8, 1887.

anywhere discoverable. Between the layers of the omentum quite an accumulation of blood was seen. A large patch of extravasated blood appeared under the diaphragm. Similar hemorrhagic effusions, but of less extent, were found at other points within the abdominal cavity. All the contained organs looked pale, but not shrunken. In the stomach no blood was found. The mucosa was strikingly bloodless.

The spleen was larger than normal, of firm consistency, and relatively rich in blood.

The liver was very pale, not enlarged, and not fatty. No hemorrhagic spots were found in its interior.

No inflammatory lesions were present, and no ruptured blood-vessel could be discovered here, or elsewhere in the body.

Before opening the chest the muscles were dissected away from the ribs. In this way a very large hemorrhagic effusion came to view beneath the fascia of the left pectoralis major, and extending directly into the substance of both pectoral muscles. The skin covering the region in question was not discolored.

The pericardial sac contained about one teaspoonful of blood-stained serous fluid, but only one small subpericardial effusion of blood was seen.

The muscular substance of the heart was pale and firm. The cardiac chambers of the left side contained a small quantity of thin, fluid blood. The cavities of the right side contained considerably more, but otherwise similar blood. Clots were nowhere to be seen. The foramen ovale was found closed. The ductus arteriosus was still pervious. All the valves were well formed, but appeared unusually delicate in structure. The calibre of the vascular trunks proceeding from or going to the heart was not abnormally small.

The lungs presented a beautiful and striking appearance. Numerous hemorrhages had occurred into the substance of the pulmonary tissue. The result was a mottled look, well-defined patches of bright red forming a sharp contrast to the marked whiteness of the healthy portions. The hemorrhagic islands were everywhere clearly defined by the boundaries of the pulmonary lobules, so that a mosaic-like appearance resulted. The hemorrhagic territories were of almost uniform size, only exceptionally involving more than two lobules. The bleeding must have been the result either of countless capillary ruptures or, more probably, extravasation by diapedesis.

On dissecting the scalp, in order to expose the calvarium, another very extensive effusion of blood was discovered. The tumor behind the ear, mentioned above, was found to consist of one mass of effused blood. The extravasated fluid occupied the tissues of the scalp, extending over all the bones of the skull, excepting only the left parietal part of the left temporal and the left half of the frontal bone. No blood had escaped beneath the pericranium, however, thus constituting a noteworthy departure from what is the rule in ordinary caput succedaneum. Both fontanelles were unusually large and quite soft.

On exposing the brain the vessels of the pia were seen to be very scantily supplied with blood. There was a moderate amount of clear serous accumulation in the subarachnoid spaces, especially toward the depending occipital region. The substance of the brain was of waxy pallor, and its consistency was above the normal. In the venous sinuses some fluid blood was seen, but again no clots were visible.

In trying to properly interpret this case, remarkable alike for the severity, the extent, and the very early occurrence of the fatal hemorrhages, we are confronted by all the uncertainty that pertains to the entire subject of hæmophilia—or the hemorrhagic diathesis, as it has been called. The infant whose history has just been given evidently bled even before birth. For the tumor about the ear was clearly the result of a hemorrhage that must have taken place while the fœtus was in utero. Whether any of the other extravasations noticed at the autopsy occurred before delivery is doubtful. At any rate, the condition of the effused blood makes it certain that they did not precede birth by many days, or even hours.

Hæmophilia is pre-eminently a hereditary disease; more so, probably, than any other known malady. Its history has shown that direct transmission is by no means always observed. Some of the worst cases apparently skipped one generation, to appear in the offspring of parents themselves seemingly free from all "bleeding" taint. Indeed, transmission by so-called transgressive heredity is held by some observers to be more common than the immediate parental variety. While, therefore, the parents of this infant were, so far as known, in good health, there is no reliable record extending farther back to show that bleeders may not have existed in older generations.

But there are other points connected with this case deserving our attention. An examination of the literature of hæmophilia shows that, even in bleeder-families, congenital hemorrhages, as well as hemorrhages during the first few days of extra-uterine life, have been very rarely observed. The cases of Winckel [1] appear to be about the best-observed ones of those that can be vouched for.

Perhaps it is proper to add the cases mentioned in an article on hæmophilia by Dr. Dunn, which was published in the *American Journal of the Medical Sciences*, January, 1883. This author briefly refers to a number of cases of bleeding in infancy. One child is alluded to as having bled from birth. Another "died of umbilical hemorrhage after bleeding fifteen days, dating from birth." Still another "had from birth spontaneous hemorrhages from nose, kidney, and bowel." All these cases concerned children belonging to families of bleeders. In no instance does the author give us a complete clinical record, or a description of post-mortem appearances.

Resuming the consideration of the writer's case, the question naturally suggests itself whether the assumption of hæmophilia is entirely justifiable, or whether we should not rather seek elsewhere for an explanation of the hemorrhagic phenomena observed. There is but one disease that, in the writer's opinion, can possibly be thought of in this connection—namely, syphilis. But reference to that disease will be made farther on.

Hæmophilia is so rarely brought to our notice in this country that it seems admissible here to quite briefly go over tolerably well-known ground, covering at least some of the leading facts relating to the disease.

Hæmophilia, then, or hæmorrhaphilia, or hæmatophilia, or morbus hæmaticus, or diathesis hæmorrhagica habitualis, are all terms used to denote a constitutional tendency to bleed, either in consequence of some slight traumatism or without discoverable cause—*i.e.*, spontaneously. A constitutional vice of this kind has for a long time been known to be hereditary in certain families, commonly called bleeders.

Hæmophilia is certainly not a disease frequently observed in America, nor does it appear to be at all common in other countries. It is much oftener seen among the fair-complexioned Anglo-Germanic races than among the darker types of Roman or Slavonic origin. The truth of this proposition must be maintained, even against Virchow's suggestion, that the greater prevalence of hæmophilia among the Teutonic races was only apparent, and due to the fact that the proportion of "writing physicians" (meaning actual, not potential, writers) was relatively so very large among the Germans.

According to Immermann's figures, out of a total of 219 families of bleeders Germany furnished 94; Great Britain, 52; North America, 23; France, 22; Russia and Poland, 10; Switzerland, 9; and other countries the remainder.

[1] Winckel's two cases of congenital hæmophilia, the hemorrhages occurring in new-born infants, are found in the Berichte und Studien aus dem Kön. sächs. Entbindungs Institut zu Dresden. Leipzig, 1874.

The great preponderance of male over female hæmophiles is a rather curious and a hitherto explained feature of the disease.

In 1877 Grandidier published records of 200 indisputable bleeder-families. These furnished 609 male hæmophiles and only 48 females, or a proportion of nearly 14 to 1. Dunn has collected 780 cases (including 631 mentioned by Grandidier), of which number 717 were males and 63 females, or a ratio of 11 to 1. Förster states that among the very young there is less numerical disparity between the two sexes.

As a rule, the first indication of the existence of a hemorrhagic diathesis occurs early in life. Thus Grandidier found that the initial hemorrhage took place within the first year of life 58 times in 95 well-authenticated cases. Nasse appears to be the only writer who distinctly states that hæmophilia may be the cause of fœtal hemorrhage.[1] Förster himself is of opinion that the "bleéder disposition" is only developed after the circulatory and other changes incident to childbirth have occurred.

Eichhorst, in his "Handbook of Practical Medicine," as well as in an excellent article on the subject in "Eulenburg's Real Encyclopædie," says that the congenital form of hæmophilia is allied to the hereditary disease. According to this accurate observer, congenital hæmophilia includes those cases in which children are bleeders, although the parents come of healthy families. Very little is known concerning the causes of congenital hæmophilia. Among those mentioned are marriage between blood-relations, phthisis, scrofula, rheumatism, or gout in the parents, and fright during pregnancy. It will be seen from this enumeration that syphilis is conspicuous by its absence from Eichhorst's list of causes. He also states that children sometimes fall victims to the disease immediately after birth, as the result of uncontrollable hemorrhage after tying the umbilical cord. Several authors have denied this, and Lange positively asserts that umbilical hemorrhage is not observed in consequence of hæmophilia. It is certainly a very exceptional occurrence. In the writer's case it will be remembered that the umbilical hemorrhage was not controllable, and became a prime factor in determining an early fatal issue of the disease.

The hemorrhagic diathesis generally lasts the entire lifetime of an individual. While it commonly leads to death at an early age, Simon and others have recorded cases where the patients lived above seventy and even ninety years of age (Simon, *Récherches sur l'hémophilie; Thèse de Paris*, 1874). Sometimes the disease is unsuspected until the extraction of a tooth or some traumatism reveals its presence by a dangerous and intractable hemorrhage. Circumcision has repeatedly led to death in this way. Scratching, leeching, cupping, scarification for vaccination, and even the application of a vesicant to the skin, have each had fatal consequences. But in most cases of hæmophilia the bleeding takes place spontaneously, as well as in consequence of some injury. Thus there may be epistaxis, profuse menorrhagia, hæmaturia, intestinal hemorrhage, hæmoptysis, bleeding from the mouth, bleeding into the auditory canal, or from the caruncula lacrymalis, or into the joints, or hemorrhage of the brain and its meninges. In a word, no tissue or organ supplied with blood can be said to be exempt from hemorrhagic accidents in this disease.

Regarding the true nature of hæmophilia nothing definite is known, and it would be far from profitable to recite the various views that have been advanced at different times to account for its morbid manifestations. Suffice it to say that opinions have hinged mainly on whether hæmophilia was dependent upon faulty blood-composition or upon abnormalities in the structure of the vessels, or upon a combination of both conditions. It is reserved for future investigations to shed light upon this obscure field of pathology.

The prognosis and treatment of hæmophilia are not pertinent to this article. It remains, therefore, to inquire whether the case related above cannot be better explained by placing it under the head of hemorrhagic syphilis of the new-born. That syphilis may lead to multiple hemorrhages in the new-born is to-day doubted by few. But the subject has only recently been carefully studied. Now, it appears that extravastion of blood into the tissues has never been observed to be the only sign of hereditary syphilis. In the writer's case, it will be remembered, no other sign of disease was discoverable.

Behrend, in 1883, described a condition to which he gave the name of hemorrhagic syphilis of the newly born. Kassowitz, Deahna, Schütz, and others confirmed his observations; while Petersen and several others opposed them, and to this day deny the existence of a hemorrhagic diathesis due to hereditary syphilis. The most recent, and probably the most important, contribution to this subject is contained in a paper read at the Fifty-ninth Congress of German Naturalists, held at Berlin, and published in the *Wiener Medizinische Wochenschrift*, November 6, 1886. Dr. Mracek, the author of the paper, is a lecturer on syphilis at the University of Vienna. His studies and observations were made under the supervision of Professor Kundrat, and extended over a period of four years. It is not necessary to follow the author into the details of his investigations. But there can no longer be any reasonable doubt that there is such a condition as "syphilis hemorrhagica neonatorum," or a hemorrhagic diathesis due to hereditary syphilis. It is equally certain, however, that these cases show numerous and well-marked anatomical lesions, chiefly concerning the blood-vessels of the body. As no such lesions were present in the writer's case, it must for this, if for no other reason, be excluded from the group of syphilitic affections of the new-born. It will have to go on record, therefore, as an instance of congenital hæmophilia, thus justifying the selection of the title for the present communication.

712 Madison Avenue.

A SHORT STUDY OF BERIBERI:

With a Report of Cases Observed in Bellevue Hospital.[1]

By J. WEST ROOSEVELT, M.D.,

Lecturer on the Principles and Practice of Medicine at the Woman's Medical College of the New York Infirmary; Visiting Physician to Bellevue Hospital; Attending Physician of Roosevelt Hospital, Out-Patient Department.

I feel that this paper must begin and end with an apology. The time allowed me for its preparation was short, and it is possible that some omissions may be found in it. The article is based largely on the papers by Scheube, and I have added to his observations any other facts I was able to obtain from other authors.

Synonyms.—Kak-ké, Beriberia, Sleeping sickness, Paneuritis endemica, Neuritis multiplex endemica, Endemic Multiple Neuritis.

Geographical distribution.—The disorder is found in portions of China and Japan, Ceylon, portions of India, Burmah, the Malay Peninsula, many islands near Asia, Brazil, some parts of Central America, the West Indies, Australia, and the Sandwich Islands.

The disease prevails endemically in these countries, and occasionally breaks out in epidemics.

The season of greatest prevalence is, according to most authors, during the hot months, when there is most decaying vegetation. In general, it seems that at seasons when malarial fevers are most common beriberi is

[1] Read before the Section on Practice of the Academy of Medicine, January 18, 1887.

also most common. Scheube states that in Japan most cases occur during the hot months of July, August, and September.

Conditions of soil.—On this point there is difference of opinion. Scheube thinks that overcrowding in cities is most favorable to the propagation of the poison, while Maclean seems to think that marshy country-districts with bad water form a good soil for it. Scheube states, and gives examples to prove, that in houses newly built on previously open ground, in or near infected cities, beriberi is very apt to appear as an epidemic.

Nationality, sex, age, occupation.—Natives in infected districts are more frequently attacked than foreigners. Males are much more often attacked than females. The disease is much commoner in adolescence and early manhood than in childhood or advanced life. It attacks all classes, but seems commoner among those who are living on poor food, and those whose occupations are sedentary, than in well-fed people who lead an active life.

Bad food and water certainly seem to predispose to the disorder, and the same may be said of anything which tends to lower the vital forces, as acute diseases, etc.

The determining cause is unknown. Certain authors think that the disease is of bacterial origin; a view which has some probability. Others, again, believe that the disorder may be the result of an unknown, but not living, specific poison. Whatever the poison is, it seems to be portable, since epidemics occur on ships, far from land, sailing from infected ports. The disease either is not contagious or is but slightly so. It is not proved, but it is probable that one case may infect a neighborhood and thus indirectly cause other cases. When epidemics occur on ships, they may be possibly the result of the poison carried in food or water, or it is possible that the infection may occur on land and the disease have a long period of incubation. The ship's crews which have suffered in this way have usually been subjected to bad hygienic surroundings, or had bad food or water, or the voyages have been protracted by storms.

The period of incubation is of unknown duration.

Symptoms.—The most characteristic symptoms of beriberi are dropsy and paralysis. In some cases the dropsy occurs alone, or at least with very slight nervous disturbances; in others the nerve-symptoms occur alone, or with but slight dropsy; and in some cases both occur simultaneously in a pronounced manner. This has led authors to describe a "dry," "wet," and "mixed" form. It must be remembered, however, that there is no sharp dividing line. Cases with predominant nervous symptoms often suddenly develop dropsy, and *vice versa*, either of the simple types passing into the *mixed* type. It is also possible for the œdema of mixed cases to subside, leaving only the paralysis behind.

The disease sometimes runs a very mild course, of which the duration may be short or long. Occasionally with pretty pronounced symptoms it pursues a slow march; sometimes it is very acute in its onset, and is rapidly fatal. If a patient be suffering from the more chronic type of the disease, an acute outbreak may at any time set in and cause death.

The onset of the disease may be marked by the occurrence of fever and symptoms of bronchitis, coryza, or catarrh of the stomach or intestines (Scheube). Many cases do not present these initial symptoms, and many authors make no allusion to them. The characteristic symptoms of the disease, in mild cases, are weariness and aching pain, with a sense of weight in the legs, with or without a certain amount of numbness in the feet; sometimes an intense desire to sleep. With these symptoms, or, in some cases, before they appear, a slight amount of œdema of the lower extremities is noticed. The œdema is not a necessary part of the disease; but, on the other hand, cases occur with œdema as the only symptom. Palpitation of the heart, some dyspnœa, epigastric or præcordial oppression, more or less anæmia (which is not constant, however), together with some mental depression, are the most marked remaining symptoms. This mild type may last for weeks, or even months or years, and it may pass into one of the more severe forms or end in complete recovery.

The severe forms differ in degree, but not in kind, from the mildest. In the type with predominant nervous symptoms, sometimes called the "dry," there is a pretty complete paralysis, with rapid atrophy of the muscles, usually of the lower extremities. The paralyzed muscles are occasionally hyperæsthetic during some period of the disease, and the hyperæsthesia may be very marked. There is frequently tenderness along the course of some of the nerve-trunks. The upper extremities may be affected like the lower, but the paralysis is rarely so complete. The abdominal muscles may also share in the paralysis. The sensorium is generally clear. Such cases may slowly recover, or may develop dropsy and thus pass into the mixed form, or die, usually from some complication, as pleurisy, endocarditis or pericarditis, or with dyspnœa and the symptoms of the malignant forms.

In "wet" cases there are the same symptoms of heaviness and weariness in the legs, but soon general anasarca, with effusion into the pericardium, pleural cavities, and peritoneal cavities, occurs. There is marked diminution in the urine. Cardiac palpitation, weak pulse, dyspnœa, præcordial or epigastric oppression, and anæmia, real or apparent, are all marked. Sometimes a profuse flow of urine, followed by disappearance of the dropsy, is noted. Paralysis is not often well marked. After the dropsy disappears this latter symptom may remain, or it may disappear before the former. Considerable emaciation occurs. Such cases may recover wholly or partially, or may develop acute symptoms and die.

In the so-called mixed form we have well-marked paralysis, with well-marked dropsy.

There remains to be described the malignant form. In this, with or without œdema, prostration, weak pulse, palpitation of the heart, dyspnœa, intense præcordial or epigastric oppression, vomiting (in some cases), great mental anxiety, restlessness, and diminished or suppressed urine, are symptoms which may attack a previously healthy man, or one already suffering from mild beriberi, and cause death in a few hours or days.

The prognosis in the malignant form is very bad. In the others it is pretty good. Relapses are common.

I must detain you to look over again some of the principal symptoms.

The nerves most commonly affected are those of the lower extremities, but those of the upper are quite frequently involved to a greater or less degree. The paralysis is not always the same in degree on both sides, if both legs are affected. Scheube has seen monoplegia and hemiplegia. The facial, glosso-pharyngeal, vagus, hypoglossal and phrenic, spinal accessory, and trigeminus have been observed to be affected. I find no record of lesion of the optic nerves.

Tactile and pain sensibility are usually diminished. Temperature and muscle-sense normal (Scheube); cramps and contractures occur in various muscles, most commonly in those of the calf. Various abnormal sensations in the limbs are common, but they are usually not to be described as pain. Fibrillary contractions of the diseased muscles are quite often seen. Trophic changes in the skin seem not to occur. The same seems true of the joints.[1] The *muscles* undergo rapid atrophy and degeneration, and may show sclerotic changes. The electrical reactions are those of degeneration, save that the galvanic excitability is always *diminished*, not increased at any time. Hiccough occurs toward the end of some fatal cases (Maclean). The bladder and rectum are never paralyzed.[2]

[1] A case of joint-lesion is described by Scheube, which is possibly of nervous origin.

[2] A rather slow flow of urine is noted in some cases.

Blood and circulatory system.—Anæmia is usual, and is often extreme. Some cases show a marked diminution in the number of red disks. Exact information in regard to the amount of hæmoglobin I have not obtained. In one of my cases, with 4,500,000 disks to the centimetre, there seemed some diminution in the hæmoglobin—the blood was paler than normal—but I was unable to estimate it accurately until late in the disease. The white cells seem relatively, but not absolutely, increased in number.

The pulse is generally weak, and may be dicrotic; the tension is low; the heart-action feeble, sometimes irregular. The circulation in the extremities is feeble, and these are cold; the frequency is above normal. Beriberi may, however, exist with a normal pulse and heart-action. Dilatation of the heart, especially the right chambers, is common; hypertrophy rare. Anæmic murmurs are often heard. Accentuation of the second sound, especially the pulmonic, is often noted. In one of my cases there was reduplication of the second sound at the base. Palpitation of the heart, aggravated by exertion, seems to be one of the commonest symptoms. Few cases occur without more or less oppression in the præcordial or epigastric regions.

Dyspnœa on exertion, or without such cause, is almost always present to a greater or less degree. *Orthopnœa* is sometimes observed. Severe dyspnœa occurs in acute outbreaks. It has been suggested that this symptom may be due to a lesion of the nerves of the lungs.

Disorders of the stomach and intestines.—Hebersmith notes a marked increase of appetite in his cases. Constipation is the rule, diarrhœa the exception. Thirst is in some cases urgent, in others not complained of. Vomiting is rare; many authors do not mention it at all. Various dyspeptic symptoms are noted in certain cases. The tongue is usually pale. Maclean states that in severe cases it may become black and dry.

The urine in "wet" cases is much diminished, or almost suppressed; sugar and albumen are absent according to most observers. In acute cases, before death, Scheube found albumen and casts and renal detritus. In "dry" cases the quantity of urine is often somewhat diminished. In "wet" cases the occurrence of free diuresis will frequently be followed by subsidence of the œdema. When the urine is diminished both the water and solids are lessened in amount.

The skin shows no specific eruptions, though purpuric spots are sometimes observed. There is none of the tendency to gangrene and suppuration observed in curvy.

In regard to the dropsy, enough has been said, save to mention that localized œdemas of portions of the subcutaneous tissues occur in some cases.

The temperature is usually normal or subnormal. Fever occurs in some of the cases.

The general nutrition usually suffers markedly. There is not only atrophy of the diseased muscles, but also emaciation. Swelling and induration of certain muscles and tendons is sometimes observed.

Pathological anatomy.—The blood remains fluid for some time after death. Fatty degeneration of the heart was found by Scheube in all his 17 cases. He also found dilatation of the right heart in 14 cases, or 70 per cent.; of both sides in 4 cases, or 20 per cent.; hypertrophy of the left ventricle in 5 cases, or 25 per cent.; of both ventricles in 4 cases, or 20 per cent. Endocarditis (acute simple) is noted in a few cases. The spleen is a little enlarged in most. Scheube also notes parenchymatous degeneration of liver and kidneys, and sometimes accumulations of nuclei in the stroma of these organs. Small abscesses have been found in the liver. General anasarca, with dropsy of the serous cavities, is common. The nerve-lesions consist of inflammation and degeneration of many peripheral nerves, the cord and brain remaining normal. The changes sometimes noted in the cord seem always post-mortem alterations. Certain muscles show degenerative changes. No lesions of the blood-vessels can be shown.

Pathogeny and pathological character.—Beriberi is probably an infectious disease. It resembles in a superficial way pernicious anæmia and myxœdema. It is hardly necessary to point out the differences between it and these disorders. It resembles still more closely some forms of scurvy. In the latter disease neuritis is rare if it is ever met with.

The points which render its infectious nature probable are its lesions and its occurrence in epidemics. The effort to show that these epidemics depend on conditions favorable to the development of scurvy fails, since people in the most varied walks of life and living on the most varied food suffer from it. Any conditions which tend to produce scurvy certainly favor the occurrence of beriberi, but they do not produce it by themselves.

How the poison is introduced into the system, whether by water, air, or food, is unknown. The period of incubation is equally unknown, but there is considerable evidence to show that it is long, possibly extending over several months. The relation of the nerve-lesions to the symptoms is easy to understand as far as the paralysis is concerned. It is also comprehensible that lesions of the vagus may produce the dyspnœa, and possibly the rapid heart-action. The dyspnœa is no doubt increased by hydro-pericardium and pleural dropsy, when these exist, and perhaps in cases by œdema of the glottis.

The dyspnœa may be further increased by lesions of the phrenic. Perhaps, also, the blood state may be a factor in its production. Whether the sense of weight in the epigastrium may be the result of vagus disease, I do not know.

The occurrence of dropsy is by no means easy to explain. We must remember that general anasarca, with ascites, pleural and pericardial effusion, may occur in beriberi within twenty-four hours of the onset, if some of the histories are to be believed. The causes which occur to me, any or all of which may take part in its production, are interference with the kidney-functions, rapid alteration in the condition of the blood, aided, perhaps, by a weak heart. Vascular changes cannot be demonstrated. Obstruction to the return through the lymphatics may possibly exist. Can there be any changes in the vaso-motor nerves which will produce dropsy? Is it not probable, at least, that the interference with renal functions may be due to deranged action of the renal nerves?

In regard to the bacterial origin of the disease, I have not yet found trustworthy evidence. Bacteria are described, but I have not been able to obtain access to the original papers describing them, and the abstracts I have read do not seem to give promise of much, with the possible exception of the report of the Dutch commission. The commission reports the discovery of a bacillus similar to, but smaller than, anthrax, found in the heart-muscle, blood, nerves, and fluid from the serous sacs. As the synopsis of the report in the *British Medical Journal*, (December 4, 1887) is short, we cannot be sure of the methods employed.

In regard to *treatment* there is but little to say. Tonics, antiscorbutics, good food, and electricity are recommended. Two mixtures, known as *treuk farrook* and *oleum nigrum*, the former of unknown composition, and the latter an empyreumatic oil, from the seeds of a plant growing in India, enjoy much reputation in that country. Tapping and aspiration may be called for in cases.

Cases observed in Bellevue Hospital.—I have to thank Dr. Ely and Dr. Freeman, of the house-staff of Bellevue Hospital, both for collecting facts and for their assistance in examining the cases whose histories I am about to relate.

The ship Henry S. Sanford lay in Hong-Kong for about two and a half months, having arrived there from Newcastle, Australia, with coal. The captain and some of the crew remained with her. She shipped some new men, including our cases, at Hong-Kong. She sailed,

with all hands well, on July 20, 1886. She went through the Straits of Timor, having passed the Philippine Islands. The Cape of Good Hope was rounded, and the first stop made was at the island of Fernando de Noronha, where they remained six or eight hours, and sent ashore for a doctor. They reached New York December 9, 1886. The food and water were both rather unusually bad, so that the men complained of them. The water used during part of the voyage was collected from the deck, which was never clean, and on which two cats and a dog were allowed to defecate. The water was stinking and contained little animals. Breakfast: Bread, containing maggots, salt meat, and coffee. Dinner: Bread, salt meat, and potatoes which soon were rotten. Supper: Bread and salt meat. Dried apples twice a week. One sailor said the food was not much worse than usual, the other that it was very bad for an American ship. The food was badly cooked. The weather was fine.

There were eighteen souls on board. Of these twelve were ill. Those who escaped were the captain's wife and two daughters, the Chinese cook, the steward, and a Russian prisoner—six in all.

The captain was the first to fall ill, three months out. He had dropsy and was unable to leave his berth, whether from paralysis or prostration is not known. He died shortly after leaving Fernando de Noronha.

The carpenter had a fight with the mate, and was laid up for a while in consequence. He was taken ill with apparently ascites alone; no paralysis nor œdema of the feet. He died.

Seaman B—— was next taken. He had bloody diarrhœa and died in Bellevue Hospital. He was the only man who had any bleeding. He had œdema, probably no paralysis. He died with dyspnœa, very pronounced, a few hours after his admission. The autopsy showed general anasarca, with pleural, pericardial, and peritoneal effusion. There was slight old, and very slight recent, endocarditis.

Seaman A—— was sick three weeks. Œdema, and paralysis questionable. He took much medicine, and died, having had a great deal of vomiting.

After this all the crew, with the exceptions noted, were sick in the same way. They had weakness and heaviness of the legs, more or less œdema, and some had dyspnœa.

Case I.—Henry D——, aged thirty-one, sailor, England, admitted December 10, 1886. Sick forty-five days. Feet swelled then, and he suffered from pain and weariness in the calves of the legs and became very easily tired. He was constipated. He did not suffer much, and continued to work until fifteen days ago, when the swelling became extreme and extended up the legs and thighs and involved the genitals. At this time he developed a dry cough, dyspnœa (which soon became severe), and some palpitation of the heart.

For past two days urine has been very much diminished; he has passed a little every hour. He has lost considerable flesh since illness began.

Physical examination showed marked general anasarca, great pallor; no signs of disease of lungs; no fluid in pleuræ, or peritoneum, or pericardium. Heart second sound at base reduplicated and loud; pulse full, slow, and strong. Temperature, normal. Urine acid, amber-colored; sp. gr., 1.016; no albumen. Liver and spleen normal size.

December 11th.—Four oz. urine; œdema less.

December 12th.—Orthopnœa and some dyspnœa. Four oz. urine.

December 13th, at 6 A.M.—Severe dyspnœa, which was followed by death at 8.30. The man was weak. The existence of actual paralysis was not established. There was numbness of the feet and legs on the day before death.

Autopsy (by Dr. Prudden).—A well-built, well-nourished man. General anasarca. Abdominal cavity contains a large amount of clear, yellow serum; peritoneal surface appears normal; right diaphragm at lower border of third rib. Moderate amount of clear, yellow serum in right pleural cavity; extensive adhesions over left pleura. About 3 oz. of serum in pericardial sac; visceral pericardium, moderate old opacity. Heart: Right ventricle contains a small clot; mitral valve in places slightly thickened; other valves normal; very slight endocardial thickening over papillary muscles; heart muscle a little pale; moderate fatty degeneration of ascending aorta. Blood in general fluid. (Note by Roosevelt: Blood was not apparently paler than normal.) Lungs: Right pleura apparently normal; right lung bronchic, congested, contains muco-pus; emphysema of middle and lower lobe; in pleura of upper part of lower lobe are numerous pins'-head, dark red, petechia spots; left lung everywhere adherent; some old adhesions, but most are fresh fibrine, some of them are apparently becoming organized; over the upper part of the lower lobe the fresh adhesions are thickest; the pleura here is besprinkled with translucent miliary nodules; the pleura contains numerous larger and smaller petechiæ; bronchi congested, mucus increased; lower lobe rather dry; upper part of upper lobe congested and œdematous; no tubercles in lung; in axillary line, on third and fourth ribs, is a subpleural, dense, tough mass of tissue, about three inches long by two inches wide; in its centre is a brown, soft mass. Spleen six inches long, four and one-half inches wide, and correspondingly thick; old adhesions over surface; cut surface shows an unusual amount of connective tissue. Left kidney a little small; capsule slightly adherent; thickness of cortex normal; markings regular and very plain. Right kidney normal. Part peritoneal tissue deeply œdematous. Stomach: mucous membrane red; otherwise normal. Bile-duct patulous. Liver about normal size; surface shows depressed areas; cut surface normal. Intestines normal; one roundworm found. Pancreas normal. Suprarenal capsules normal. Mesenteric glands swollen. Brain and membranes and vessels appear normal. Glottis: mucous membrane a little swollen, suggesting œdema, now disappeared. A little petechial spot on posterior surface of epiglottis. The nerves were not examined.

Case II.—James L——, aged forty-nine years, sailor; Sweden; admitted December 11, 1886. Six weeks ago patient was taken sick, and has been unable to work since then. First symptoms were stiffness and soreness about the ankles, followed by slight swelling of the legs. He became quickly prostrated. For last month much troubled with dyspnœa and orthopnœa, and marked palpitation of the heart and epigastric oppression. Three weeks ago began to have a cough, and expectorated a little liquid containing pellets. He has suffered from some headache and slight blurring of the sight; no muscæ volitantes. From the beginning of his illness his appetite was poor, his bowels constipated, he had occasional nausea and vomiting, and he slept badly because of dyspnœa. He noticed nothing peculiar about his urine.

Physical Examination.—Well-nourished muscular man; complexion pale, with slight yellowish shade of skin; sclerotics normal; tongue pale; gums rather red and soft; a yellow, dirty deposit about one tooth; no tendency to bleed; general subcutaneous œdema; lower extremities markedly œdematous, and genitals slightly so; visible pulsation of carotids and at the sternal notch; pulse small, slow in rise and fall, and strong. Heart: Apex in normal position; area of superficial and deep dulness normal; low-pitched, blowing, systolic murmur, audible over the whole base of the heart, most intense over the third left costal cartilage, not heard in vessels; second sound at base loud and rough, suggesting reduplication; venous hum in the neck. Lungs (both lungs anteriorly): dulness, prolonged expiration, subcrepitant râles, and coughing, from apex to third rib; behind (both lungs from angle of scapulæ down), flatness,

absent voice and breathing, with exaggerated voice at upper level of flat area. Liver and spleen normal size; no signs of ascites. Ophthalmoscopic examination: Normal fundus. Blood contains a nearly normal number of corpuscles; the color is a little pale; a scanty, pink, papular eruption on shoulders and back; no hemorrhages into skin or mucous membranes. Urine amber, acid; specific gravity, 1.014; no albumen.

Ordered iron and bitartrate of potassium, and occasional purges and fruit.

December 14th.—Forty ounces urine in twenty-four hours; somewhat less œdema; 4,500,000 corpuscles in a centimetre of blood; oppression in chest and epigastrium marked; not much dyspnœa.

December 15th.—Fifty ounces of urine; œdema less; marked paresis of lower extremities is noted; patellar reflex diminished.

December 16th—Fifty-eight ounces of urine; marked paralysis of flexors of the feet; slight anæsthesia of feet.

From this date until December 29th the œdema steadily diminished, the urine averaging about eighty-five ounces *per diem*. Nothing noteworthy occurred. There had been no fever up to this date.

December 29th.—The temperature began to rise and reached 105° that evening. It continued slightly above normal until January 3d, when it again rose, reaching 103° that evening. It fell slowly, and since then has remained practically normal. The patient felt no worse during this run of fever, and there seemed nothing on physical examination to account for it.

On January 3d some difficulty is noted in starting to pass water. When the stream comes it is normal.

January 10th.—Improvement in strength of legs. No anæsthesia; no œdema. Legs have grown thinner. Some tenderness in calf muscles. No fluid in chest. No heart murmur. Tender points found over both sciatic nerves between the ischial tuberosity and the trochanter, also over both median nerves at the wrist, and over the upper part of the outer border of the supinator longus muscle in both arms. It is not known that these points did not exist before.

The patient can stand without much support. When walking, with assistance, his feet droop and the toes drag until the step is nearly completed, when by a jerk of the thigh he throws the foot clear of the floor. The toes touch the floor first as the foot is put down. When lying in bed the feet are extended, and the soles turned somewhat in. The toes are partly flexed, from paralysis of their muscles. There is no spasm. The patellar reflex remains slight but distinct.

January 15th.—Strength somewhat better. Three days ago the potass. bitartrat. was stopped. To-day there is a little œdema of the ankles. Bitartrate ordered again.

January 17th.—There is complete paralysis of the flexors of the foot and extensors of the toes. The calf muscles still have a little strength. There is considerable atrophy of all the muscles of the legs. The thigh muscles are also somewhat atrophic and paretic. Arms not affected. There is slight œdema over the external malleoli of both sides. No fluid in either chest or abdomen. Heart-sounds normal. Still some oppression in epigastric region.

Dr. Seguin kindly made an examination of the patient, and found a quantitative diminution in electric, with sluggish contractility of all of the paralyzed muscles.

Specimens of the blood of the patient were frequently examined for bacteria, with negative results, as far as the microscopical examination would show. Two sterilized gelatine tubes were inoculated by me with blood, the usual precautions being observed. A Koch syringe was also filled with fluid from the pleural cavities. These were submitted to Dr. T. M. Prudden, whose report on them is as follows:

"The specimens received from Dr. Roosevelt were two gelatine tubes inoculated with blood, and a sterilized Koch's balloon syringe filled with reddish turbid fluid from pleural cavity. Gelatine culture-plates were at once made from the blood specimens, and four gelatine plates from a small quantity of the pleural fluid. Six agar-agar plates were also made from the pleural fluid, put into the thermostat, and kept, with frequent examinations, at a temperature of 36.5° C., for eight days. The gelatine plates were kept at about 25° C. for the same time. In none of the plate cultures was there any bacterial growth whatsoever. A large number of cover-glass preparations was made in the usual way from the pleural exudation, and neither by the ordinary fuchsine and gentian violet staining, nor by Gram's method, could bacteria of any kind be detected.

"Thus the result of both the morphological and biological methods of examination of the pleural exudation, and the biological examination of the blood was entirely negative."

My attention was called by Dr. Ely to a condition of the red blood-disks observed in a number of fresh specimens when examined with a high power. Numbers of the corpuscles showed in their centres colorless portions which were of various shapes. Some were round, others were in the shape of a letter S, others were oblong, or dumb-bell in form. Beyond this nothing peculiar could be seen in the blood by the most careful examination. The earlier specimens examined showed perhaps a rather scanty fibrin network, and a somewhat diminished tendency of the disks to form rouleaux, but the correctness of this observation is rather doubtful. An estimation of the hæmoglobin, made June 10th, showed a normal amount. Gower's hæmoglobinometer was used.

Through the kindness of the physicians of the Brooklyn City Hospital, I am enabled to state that the mate of the vessel, who was treated there, suffered œdema and coldness of the feet, with weariness and numbness. He was not laid up. He had also cardiac valvular disease, apparently of long standing. He asserts that all the sick men suffered in the same way.

The question naturally arises, are the cases beriberi? One expects to find scurvy in ship epidemics. We had here certainly conditions which favored and might produce scurvy. As against the diagnosis of scurvy, I offer the following points: One man only bled, and he had only a bloody diarrhœa. There was no bleeding from the gums in any case. The condition of the gums in Case II. was no worse than that often seen in people who use no tooth-brush. The petechial spots observed in the pleura of Case I. are not much of an argument in favor of scurvy. Paralysis, as far as I can ascertain, does not occur in scurvy. Scurvy, however, may occur, with œdema as the most prominent symptom. The *captain was the first man ill.* This is a fact of importance when we think of the probability of scurvy. Finally, the mode of death of Case I., and the complete symptoms of Case II., are singularly like beriberi. The ship sailed from an infected port, and the food and water on her predisposed to an outbreak of beriberi as much as scurvy.

Progress of Medical Science.

Ignipuncture as a Method of Surgical Treatment of Chronic Cervical Adenitis.—Dr. Dumenil reports nine cases of enlarged glands of the neck among soldiers treated by the introduction of a platinum wire into the gland and the practice of galvano-cautery (*Philadelphia Medical Times*, November 27, 1886). In some cases there was a discharge of caseous matter and free suppuration for a few days; in others this did not occur. In both groups of cases the glands rapidly underwent resolution, and only a trifling scar was left by the operation. Although the most radical and rapid method of removing these glands would be by the surgeon's knife, which may now be done with antiseptic appliances even by the most timid, there still are cases in which deep cauterization has the advantage; for instance, where the patient recoils from ablation, or where the tumors are multiple. In case of doubt as to the malignant character of a tumor in these regions, probably prompt extirpation would be the most advisable plan of treatment. At the present day this affection is no longer considered as a strumous engorgement or scrofulous adenitis, but as a local tuberculosis. The lymphatic glands of the neck receive the lymphatic vessels coming from the buccal, nasal, and pharyngeal cavities, and are specially liable to receive infectious particles which are carried by the air. The numerous diverticula which are met with in these regions, and the frequent lesions, particularly of the gums, constitute ports of entry into which the infectious elements may enter with the greatest facility. The marked frequency among soldiers is due partly to bad hygiene, and particularly to neglect of the bucco-pharyngeal cavity. As the affection is found very frequently among quite vigorous subjects whose general health is good, and in whom no hereditary predisposition exists, it appears evident that the local conditions are quite sufficient to explain the production of tuberculous adenitis. In making the cauterization, a filiform galvano-cautery surmounted by a button was first employed, but afterward was replaced by a simple platinum point, which was made to penetrate to the centre or traverse the tumor in one or more directions. Cold compresses were then applied. Anæsthetics were not needed. In all the cases except one the ignipuncture gave satisfactory results. The exceptional case passed from observation without having shown any diminution in the glands, but his general health remained good. In almost all the cases the glands were in the way of becoming caseous, and it is in this condition that good results have been the most rapid and the most striking.

Conditions which Aggravate Syphilis.—Fournier maintains that certain physical conditions in the person infected have more to do with the gravity of syphilis than the quality of the syphilitic virus. These conditions he discusses as follows: 1. Alcoholism. A powerful factor in increasing the virulence of this affection, favoring the spreading and increasing the intensity of the cutaneous lesions; producing severe symptoms, tertiary in character, early in the secondary stage; creating special types of eruption, malignant, and involving large areas of skin surface, causing more frequent outbreaks of the syphilides, depressing the system, and finally predisposing to early nervous manifestations, and causing deposits in the brain and spinal marrow. 2. Age. Syphilis is always severe at the two extremes of life. In the infant the disease, whether inherited, congenital, or acquired, is very frequently fatal, in striking contrast with its benignity in the child two, five, or six years of age. In the adult it is usually mild. After fifty or fifty-five years the disease begins to be severe, and in old age it is extremely virulent. 3. Scrofula and tuberculosis act on syphilis, and give rise to special symptoms, and at the same time syphilis exerts an unfavorable influence on those diseases. In those cases the syphilides have a moist, suppurating, and fistulous character; ocular, osseous, and articular lesions are frequently present; and the larynx, pharynx, and nose are early and deeply involved. In scrofulous subjects a particular mixed kind of inflammation of the glands is noticed, and in patients with tuberculous tendency pulmonary lesions are very often hastened. 4. Malaria also predisposes to grave forms of syphilis, as seen in those affected with malarial toxæmia. 5. All agents which depress the vital economy can serve as factors of virulence in syphilis, such as extreme poverty, bad hygiene, insufficient alimentation, prolonged lactation, fatigue, mental worry, etc.—*Quarterly Compend. Med. Sciences.*

The Blood at Birth.—Dr. F. Krüger, of Dorpat, has been investigating the condition of the blood of the fœtus at birth, and comparing its properties and composition with the maternal blood. The subject has been studied before. In some respects the present research confirms the previous ones—notably those of Becquerel and Rodier. Like those authors, Krüger finds a very slight comparative increase in the total solid constituents of the blood at this early period of existence; but he shows that in fibrine fœtal blood is markedly deficient, viz., about one-third of that contained in maternal blood. The amount of hæmoglobin is about the same as that of maternal blood, but it increases in quantity in the infant for some time after birth. Unlike the adult, there is no notable difference in the composition of blood in the two sexes. Fœtal blood at the moment of birth has a great tendency to coagulate, but coagulates slowly, *i.e.*, the process begins early, but continues for a long time before it is completed. Inquiring into the reason of this, he directed attention to the factors which, according to Schmidt, are essential to coagulation, viz., the leucocytes and blood-plasma. Three possibilities presented themselves: either there is a diminished activity of the blood-plasma in causing the liberation of "ferment" from the corpuscles, or the number of leucocytes must be less than in the adult, or these corpuscles part with the ferment less readily. On the first hypothesis, coagulation ought not to be quickened on the addition to the plasma of more lymph-corpuscles; but the contrary is the case. Nor is there any diminution in leucocytes, the absolute and relative number per cubic millimetre being the same as in the adult. It is concluded, therefore, that the reason of the slowness of coagulation of fœtal blood depends on the nature of the white corpuscles, and their slighter readiness to break up.—*The Lancet.*

Tuberculosis of the Bladder.—Tuberculosis of the bladder is, according to Guyon, relatively frequent. Dr. Boursier, assistant to Guyon, has collected thirty-seven cases. According to this author, tuberculosis of the urinary receptacle can show itself under two forms, primary or secondary. In the first case the malady is marked by frequent desire to pass water at night. The patient gets up three or four times; pain is felt during the act of evacuation, and especially at the close. With the last drops of urine appear often, and in a more advanced stage of the disease, small clots of blood. This hæmaturia is nearly always the indication to consult the medical man. Micturition, which is so frequent and often imperious, is, as has been already said, attended with a burning sensation, which remains a considerable time after, and often excites spasm of the neck of the bladder, thereby producing exceedingly painful retention. At other times the patient will be troubled with incontinence, which as often results from simple over-distention of the bladder, from the fear of the patient, who seeks to delay the emission as long as possible. However, the author thinks that the incontinence observed in children might be the result of tuberculosis of the bladder. The duration of the affection is very variable — five, ten, fifteen, or twenty years.

THE EFFECT OF EXCESSIVE ILLUMINATION UPON THE EYE.

THE exposure of the eye to intense light has been attended with many curious and unfortunate results. In the case of Professor J. Plateau, of the University of Ghent, who while trying to observe the effects of irritation of the retina gazed steadily at the sun for twenty seconds, a chronic irido choroiditis developed, which ended eventually in total blindness. Dr. J. A. Andrews, in an article upon this subject (*Trans. of Amer. Ophthalmol. Soc.*, 1886), collects a number of cases in which choroiditis and retinitis occurred in persons who had observed an eclipse of the sun. The single flash of a sun reflector has been known to cause retinitis. Scotomata, amblyopia, and other temporary visual disturbances of a functional character have been frequently noted. M. Reich has described a curious epidemic of snow-blindness which occurred among a body of laborers engaged in clearing a way through masses of snow which obstructed the road between Passanaur and Mleti, in the Caucasus. The rays of the sun, reflected from the vast stretches of snow on every side, produced an intense glare of light, which the unaccustomed eye could not support without the protection of dark glasses. A few of the sturdiest among the laborers were able to work with impunity, but the majority, and especially the weakly and anæmic, suffered severely in their eyes, in spite of the various devices to protect them from the light. Among seventy strongly marked cases, thirty were so severe that the men were absolutely unable to continue their work or to find their way home. They were collected in a covered place, where Reich found them on his arrival prone on their faces, striving to hide their eyes from the light, and crying out from pain. Photophobia was present in all the cases. Hyperæmia of the conjunctiva, with more or less injection of the ciliary vessels, and even chemosis, was found in all severe cases. Recovery was gradual, but complete. Dr. W. C. Rockliffe (*Ophthal. Rev.*, September, 1882, quoted by Dr. Andrews) records a case of acute conjunctivitis brought on by exposure of the eyes to a 3,000 candle-power electric light. Dr. Emrys-Jones and Dr. David Little have both reported instances showing that workmen or others who expose the naked eye to an arc light of great intensity are liable to have conjunctivitis, as well as more serious ocular disturbances. It is estimated that exposure of the naked eye for one minute to an arc light of 2,000 candles will cause conjunctivitis. The violet or orange lights are said to be less injurious than the normal white light.

The light of lightning is too transient to cause any injury from simple retinal over-irritation; but it is known that cataracts sometimes follow lightning-strokes, and these are believed to be produced by some physico-chemical influence.

Glass-blowers suffer from an opacity of the lens brought not by the light, but the intense radiant heat (148° F.) to which they are exposed during their work. Dr. Andrews found such opacities in 4.5 per cent. of men under thirty-eight years of age, and twenty per cent. in men above that age. Dr. Meyhoefer found nine per cent. among men under forty.

Of all forms of artificial illumination the incandescent electric light, so far as facts now go, is the best. Among 1,100 persons who worked by this light, Dr. Andrews found not a single case of injury. On the other hand many persons testified to the fact that they could work longer by it with less fatigue than with the gas or oil light. This is due, it is found, to the steadiness, absence of heat, and perhaps the greater proportion of violet rays. Short-sighted persons are, in particular, benefited by the use of the incandescent lamp.

EDUCATION AND PATENT MEDICINE.

A CORRESPONDENT asks us how much money is expended annually for patent medicines, and how the expenditure compares with that for educational purposes.

In the year 1882–3 there was expended for educational purposes upward of $76,000,000, or, including the amounts put in sites, buildings, furniture, apparatus, etc., $95,770,712 (*Report of the Commissioners of Education*, 1882, p. xix.). The amount paid for teachers' salaries is $58,272,204. The amount paid for patent medicines annually in this country is about $22,000,000, and between five and eight millions are paid annually to newspapers for advertising them. In England the tax alone on patent medicine amounts to $600,000 annually.

It will be seen that the people of this country pay annually nearly one-third as much for drugs to poison their stomachs as they do for instruction to enlighten their minds.

The *Western Druggist* has given some interesting figures which bear further upon this question: "More patent medicines proportionately are sold in the United States than elsewhere. The great middle class buys most of them.

"The smaller country newspapers subsist largely upon advertisements of these 'remedies,' and at least $100,000,000 have been paid newspapers during the last two decades, while upward of $5,000,000 have been expended in rock and fence advertisements.

"The field for new patent medicines is narrowed every day. Cathartic pills and sarsaparillas do not succeed readily, because so many well-established specimens occupy the field. Until the stamp tax was abolished patent medicines yielded the Government $1,800,000 annually. The census of 1880 shows that there were then 563 establishments in this line in the United States, employing 4,015 operatives; that the capital invested was $10,620-

000, and that the value of the annual output was $14,682,000. New York stood first in the amount of capital invested ($3,512,430), and in annual output (nearly $4,500,000); Pennsylvania second in capital invested, $2,000,000, and third in annual output, $1,000,000; Missouri third in capital, $1,500,000, and fourth in annual output, $750,000; Ohio fourth in capital, $570,000, and fifth in annual output, $450,000; Massachusetts fifth in capital, $521,000, and second in annual output, $1,500,000."

ENTEROPTOSIS—A NEWLY DESCRIBED MORBID CONDITION.

If King Solomon had studied the medical art, he would probably never have contributed to proverbial philosophy an observation so inapt as that in which he dwells upon the general absence of sub-solar novelty. The activity and acumen with which medical investigations are being pushed lead every year to some fresh increment of knowledge and some novel interpretation of facts, quite in defiance of the wise king's aphorism. From Solomon to M. Glenard, of Paris, France, is a considerable step both in time and perhaps in intellectuality; but M. Glenard believes that he has something new, and such persons controvert Solomon and, naturally, in the same connection, challenge contemporaneous attention.

Glenard's thesis is this: *Application de la méthode naturelle à l'analyse de la dyspepsie nerveuse. Détermination d'une espèce De l'Enteroptose. Lyon*, 1885. *Neurasthénie et Enteroptose, Soc. Médicale des Hôpitaux de Paris, Mai*, 1886 (*Revue de Médecine*, January, 1887). The most common form of what is known as neurasthenia is the gastric type, or, as it is sometimes called, nervous dyspepsia. In nervous dyspepsia or gastric neurasthenia there always exists a morbid anatomical condition appreciable on physical research. This condition is given the name of enteroptosis, or prolapse of the intestinal mass.

"Enteroptosis" causes (1) asthenic symptoms, such as assitude, malaise, weakness over the stomach and loins; (2) epigastric symptoms, such as feelings of weight, hollowness, squeezing, boulimia; (3) gastric symptoms of tympanites, and oppression, pain, burning, cramps, and vomiting; finally (4) general neurasthenic symptoms referable to the head and spinal cord, such as mental irritability, hypochondriasis, etc. In other words, the condition of enteroptosis produces the phenomena generally recognized as those of gastric neurasthenia.

M. Glenard bases his views upon the analysis of 200 cases, in all of which he lays the trouble to the prolapse of the abdominal viscera: 1st, Because he finds objective signs of such ptosis in these states; 2d, because the symptoms accord with what might be expected from it; and 3d, because relief of the prolapse relieves the symptoms.

The objective signs do not appear to us to be very well described; but it is stated by Glenard that in cases of confirmed neurasthenia a methodic exploration of the mesogastrium brings out four important signs: 1st, Flaccidity of the abdominal walls, loss of tension of the muscles, or "*abdominal hypostasis;*" 2d, prolapse or falling downward of the intestinal mass, *enteroptosis*. As confirmatory signs there are found in one-third of the cases evidence of prolapse of some of the viscera, such as floating kidney, mobile liver, mobile spleen, narrowing of the colon from twisting with strain upon the ligaments; finally, gastric atony, dilatation, and prolapse.

The falling of the intestines and other abdominal viscera puts a strain upon the ligaments suspending them, and also, in the case of the stomach and intestine, changes their calibre, and produces constrictions and dilatations at different points. The result is the whole train of chronic symptoms recognized as nervous dyspepsia, neurasthenia, and hypochondriasis.

Although a more or less general prolapse may exist, we are told that the fundamental and constant lesion in enteroptosis is a prolapse of the first arch of the colon, *i.e.*, of the angle at the junction of the ascending and transverse colon. This causes a prolapse and atony of the stomach, which, in turn, tends to weaken further the proper support to the colon, and so the process goes on. But the essence of Glenard's view seems to be that a prolapse of the colon is the cause of a large number of neurasthenic symptoms.

The 200 cases cited show at once that Glenard has been studying a peculiar class of nervous troubles. Among the 200 there were 123 in which the symptoms developed after accouchement, as the result of the flaccidity of the abdominal walls, 19 were of traumatic origin, 4 post-inflammatory, and 54 post-dyspeptic. Among the 200 cases there were 157 women and 43 men.

Mobile kidneys were found in the extraordinary proportion of thirty per cent.

The indications for treatment are: 1st, To combat the enteroptosis and abdominal tension by hypogastric support; 2d, to combat the enterostenosis by laxatives; and 3d, to give tone to the abdominal viscera by all possible medicinal, mechanical, and hygienic measures.

One of the best empirical treatments is that by rest, feeding, and massage.

A YEAR OF CREMATION.

The annual report of the New York Cremation Society is of interest to everyone, though this method of disposing of the dead is by no means an accepted custom. The secretary's figures show that the Society has one hundred and thirty-two active members, and a total membership of one hundred and ninety. But two have renounced their allegiance, while two have died. The latter showed their fidelity not only unto but even after death, as their bodies were incinerated at Fresh Pond. The year's receipts were over four hundred dollars, and the Society has now over twelve hundred dollars to its credit.

The report of the president expressed satisfaction at the work of the year. It says, in part: "During the year just ended we have more than held our own as to numbers and resources. Aside from this, it has been a year of inactivity. Call it a year of waiting—of waiting on events and developments at the Fresh Pond Crematory." We learn that eighty-four incinerations have been performed during the past year, and the crematory has earned over two thousand dollars. Nevertheless, the Society finds itself financially embarrassed and asks from its members and friends, "a moderate contribution in the shape

of a temporary loan," so as to have a reserve fund for emergencies. The crematory itself is regarded as "not elegant, but sufficient for all practical purposes," certainly a practical remark.

A common-sense spirit pervades the entire report. The managers of the Society have not adopted the rôle of fanatics. They have placed before the public their sincere convictions, and have allowed the question to stand on its own merits. Hence, they may naturally claim that the progress made is permanent. Their modes of procedure might well be followed by would-be reformers in general. In regard to their hopes for the future, the report says: "Cremation has gone quietly into operation without opposition or hindrance from any source and without serious difficulty as to practical details. That an entire change in the customs of a people in the important and solemn matter of disposing of the dead should have been allowed in this way is certainly creditable to modern toleration. Considering that as yet it is but a feeble minority that prefer to give their bodies to the elements of fire to purify and consume, instead of giving them to foul the other three elements, we must admit that it is very generous of the majority to let us have our own way, which we trust will soon be the way of all."

MEDICAL LEGISLATION IN OHIO.

The State of Ohio has been mediæval in its legislation regarding all matters of State medicine. It was a long time in getting a State Board of Health, and all efforts to secure a respectably good medical law are antagonized with equal persistency and ignorance. There is now a medical bill before the legislature which provides for registering physicians and regulating the practice of medicine. We cannot say whether the bill is a perfect one or not, but the main principle is correct, and the arguments urged against it by the daily press of the State show a most extraordinary degree of ignorance of the subject of medical legislation as well as of the general state of medical practice. The State regulation of this practice, so as to secure citizens against the swindlers and the ignorant, is a perfectly well-tried and approved feature of social polity. And laws tending to further this deserve the support of wise legislators. We trust that Ohio will get a suitable law, and that the drivellings of such editorial writers as have been commenting on the matter in the *Toledo Blade* will have no effect. The answer to all such persons is the practically good results of sound medical laws already attained in Illinois and many other States.

THE LAWS OF INFECTION.

Among the more positive results relating to the study of pathogenic micro-organisms achieved during the past year have been those of Watson Cheyne and of Wyssokowitsch. They bear upon the laws regulating infection, and demonstrate almost absolutely the fact that there is really in some diseases a battle between the tissue-cells and the bacteria. Mr. Cheyne, in a research intended to discover the dosage and virulence of infective germs, found that the initial dose of virus was of great importance, and in several instances exercised a marked influence on the course and virulence of the disease. In a summary in the *British Medical Journal* it is stated that various laws were made out—for example, the pathogenic dose of a virus varies inversely with the predisposition of the animal to the disease in question; in animals not very susceptible to a disease the severity of the affection varies directly within certain limits with the amount of the virus introduced, etc. It was found that in some cases a small dose of a virus produced only a local effect, while a larger dose killed the animal, and the small dose might protect the animal from the fatal effect of a subsequent large dose. Although it is as yet impossible to measure predisposition, and thus to decide the dose for any individual, nevertheless the knowledge of the relation between these two factors is of the utmost importance, as throwing light on the mode of spread of epidemics; while the fact that a considerable quantity of the virus is in many cases necessary for the production of a disease explains many anomalies, and affords indications for preventive measures.

The results of the more recent work in injecting micro-organisms into the blood are given in the *British Medical Journal*. In 1874, Traube and Gscheidlen found that, if a quantitty of putrid fluid were injected into the blood of rabbits and dogs, and the blood taken twenty-four hours later, with aseptic precautions, no organisms developed in it, showing that the bacteria introduced had disappeared from the blood, or had been destroyed in it in that short time. Some years later, Watson Cheyne found also that saprophytic bacteria, when injected into the blood-stream of rabbits, disappeared from the blood in twenty-four or forty-eight hours, and he concluded that they had been destroyed in it. Pursuing the subject further, he found that, if larger quantities were introduced, along with the fluid in which they grew, they were able to survive for a longer time, and that the same was the case with smaller quantities, if the animals experimented on had been previously weakened in health by the administration of repeated doses of phosphorus or other poisons. He explained this fact on the supposition that the products introduced with the larger quantities of putrefying fluid, or the poisons previously administered, had so weakened the vitality of the blood and tissues that they were no longer able to destroy the bacteria. Wyssokowitsch has repeated the experiments, and has come in the main to the same conclusions as Watson Cheyne, but he has added several interesting observations. In the previous researches mixtures of bacteria, probably not containing spores, were employed; but Wyssokowitsch used pure cultivations of known organisms, and found that, while sporeless bacteria were rapidly destroyed, the spores could retain their vitality in the body for a long time, and remained in the tissues in a dormant state. In both cases the blood very rapidly became freed from organisms, but the spores were deposited chiefly in the liver, spleen, and medulla of bone, and were apparently taken up by the endothelial cells of the capillaries, in which they were found imbedded many days after their introduction. In one case a few spores of bacillus subtilis were found alive in the liver seventy-eight days after their injection, although none were present in the other tissues or organs. Wyssokowitsch's results with pathogenic organisms are very interesting. When only a few anthrax bacilli were injected, they dis-

appeared from the blood almost completely for some hours, but after twenty-four hours they began to appear again, and increased in number till the death of the animal. When they were introduced in large numbers, this disappearance from the blood was not very marked. Apparently all bacteria tend to be deposited in the organs before mentioned, and in the case of non-pathogenic organisms are there rapidly destroyed unless spores are present. In the case of pathogenic bacteria, this deposit and destruction of the organisms is incomplete, and they very soon gain the upper hand, and again spread into and multiply in the blood. We have thus in the structure of the vascular walls, and especially in the endothelial cells of the capillaries, a protective arrangement against any bacteria which may find their way into the blood. These organisms are deposited and retained in or between the endothelial cells of the capillaries, especially in the organs in which the circulation of the blood is slowest. Then begins a battle between the cells and the bacteria, which results either in the destruction of the bacteria or of the cells, which in the latter case provide a pabulum for the further development of the organisms. Those bacteria which, as a rule, gain the victory must be looked on as a specific bacteria, pathogenic for the class of animal experimented on.

IS CONSUMPTION ON THE DECREASE?

From a practical and statistical study of pulmonary consumption, chiefly as occurring in the city of Philadelphia, Dr. Thomas J. Mays[1] has been led to take a rather more hopeful view of the disease than can be attributed to the majority of medical men. The author finds that in Philadelphia alone, during the last ten years, 26,180 persons have died of pulmonary consumption, and then observes that the "deaths of its many victims scarcely excite more than a passing ripple of alarm in the public mind." In New York, it is our opinion that "the public mind" is so thoroughly inured to the large mortality from phthisis, as to quite take it for granted, without even being moved by passing ripples of alarm, such as obtain in Philadelphia.

Now, it is only too true that the mortality statistics of phthisis speak with sorrowful eloquence of a frightful waste of human life. And it is likewise already apparent that the new bacterial doctrines concerning the etiology of this disease have helped us very little, if at all, in our efforts to check this enormous mortality.

In spite of all this, Dr. Mays believes that phthisis is decreasing, and he is hopeful of a still better time to come. He alludes to the often-cited allegations of professional explorers and discoverers, that the savage does not die of consumption. The disease is "principally engendered by some of the influences which have transformed man from a savage into a civilized being." But Dr. Mays does not advise a return to primitive life, believing that attention to well-known hygienic laws regarding shelter, occupation, food, clothing, and the like, will suffice to mitigate the ravages of consumption.

Besides this, he urges the erection of hospitals exclusively devoted to the treatment of "chest diseases," which may be presumed to mean chronic affections of the lungs. He also accuses the profession of apathy concerning consumption and consumptives, claiming that this is "largely due to a lack of hospital facilities, where these cases can be studied as systematically and as advantageously as other diseases are." There is doubtless much truth in this statement, but as regards the evidence adduced by him in favor of the view that phthisis is already on the decrease, it rests on the slender basis of statistics gathered from a few American cities. According to him, the figures show "that, on the whole, there is a gradual decrease in the number of deaths from pulmonary consumption." We must take issue with Dr. Mays on this point, believing that he has not presented nearly enough statistical evidence to justify any such wide generalization. On the contrary, the very influences which he has mentioned as active in the production of phthisis, are surely more potent for evil in our day than they ever were, or could have been, before. For they belong to modern industrialism, to material progress, to the harsh strife of competition; in a word, they are apparently inseparable from the growth and spread of what we call "civilized life."

An examination of the statistics of all countries will show that, if the mortality from consumption is not increasing, it is certainly not on the wane. Nevertheless, we are inclined to agree with the author when he says that, "notwithstanding the fact that pulmonary consumption causes nearly one-fifth of the whole number of deaths in this country, the picture is not grave enough to warrant us in drawing pessimistic conclusions concerning its final influence on the human race."

The diffusion among the masses of hygienic knowledge will tend to eventually lessen the mortality from this, as well as from other of the more preventable diseases. But between this confidence in the future and the actual decrease of phthisis at present, as alleged by Dr. Mays, there is still a wide gulf, to be bridged over by education and prophylaxis.

A SPECIMEN OF HAHNEMANNIAN HOMŒOPATHY.

We have read with great profit the last issue of *The Hahnemannian Monthly*, a journal devoted presumably to the propagation of homœopathy and the homœopathic practice. The six original articles with which the issue opens are striking illustrations of how little homœopathy there may be in the practice aforesaid. The first treats of fatty heart, and the treatment advised is mainly hygienic—"symptoms as they arise should be treated with the properly selected homœopathic remedy," but it is admttted that the prognosis is bad, *i.e.*, the remedies are futile. The next article is devoted to showing the value of boroglyceride in certain surgical affections. The third article is on climate and phthisis, the fourth describes how the writer gave a three-drachm vial of atropin, ten drachms, to a patient with singultus, until the throat was dry and the pupils dilated. He next gave one-fifth of a gram of pilocarpin, then lachesis, then nux vomica, then ignatia, then hyoscyamus, and then gelseminum in one minim doses. At the end of three months the patient was well, despite the polytherapy. The last communication is upon belladonna, agaricus,

[1] A Study of Pulmonary Consumption in the City of Philadelphia. Read before the College of Physicians of Philadelphia.

and borax, and reads a good deal like the real jargon of dogmatic therapeutics.

The perusal of the articles above referred to leads one to ask how much of the real Hahnemannism there is nowadays among the readers of our valuable contemporary. There is certainly more climate, pilocarpin, and strong nervines and narcotics than anything else in the last issue.

News of the Week.

Congress is Asked to give $45,000 for the International Medical Congress, and it ought to do it.

Cholera has been Prevailing in Calcutta to an alarming extent. The mortality for the month of December last was not far from four hundred cases.

An Attempt is being made to abolish the Kansas State Board of Health.

An Important Medico-legal Decision.—In the Superior Civil Court at Boston, recently, a mother and her four children individually sued the landlord to recover damages for sickness contracted because of the poor sanitary condition of the house, and in the care of the family during their sickness from diphtheria. Damages in each case were awarded, the mother receiving $1,600, and the children, $700, $300, $250, and $200, respectively. This is a unique case, and is valuable as a precedent.

A great Medical Congress of the physicians of Russia was held in Moscow, beginning January 4th. Over a thousand medical men were present.

The Medical Society of Kings County is to have a building of its own. At a meeting on February 15th the Society adopted the report of a committee recommending the purchase of land and buildings at No. 336 Bridge Street, Brooklyn. Dr. Thallon, Dr. Matheson, Dr. Jewett, Dr. Hunt, and Dr. Hutchins were appointed trustees to make this purchase, and were empowered to receive subscriptions, not to exceed $15,000. It is intended to build a large meeting hall and transfer to it the Society's library. There will also be accommodations provided for the Superintendent of Nurses.

Transplanting the Eye of a Rabbit.—An attempt recently made in this city, by Dr. C. H. May, to transplant the eye of a rabbit to the orbit of a man has proved unsuccessful. Unless some radical improvement in technique can be devised, the operation will never probably become a practicable one.

The International Medical Congress.—Dr. Mariano Semmola, Professor of Experimental Therapeutics in the University of Naples, has consented to deliver one of the "General Addresses" before the International Medical Congress at Washington. He has chosen for his subject "Bacteriology and its Clinical Therapeutics."

Dr. J. F. M. Geddings, of Charleston, S. C., died recently in the fifty-eighth year of his age.

A Medical Peer.—Professor Billroth, of Vienna, has been elevated to the peerage, and *à propos* the English medical journals lament the fact tha England alone refuses to make peers out of doctors

A Question of Prejudice.—The *Southern Clinic* says: "In looking over the proceedings of the State Examining Board for the past two years we find that, out of 29 applicants from the University of Virginia and 19 from the Medical College of Virginia, in these two years, not a single applicant from these two Virginia schools has failed to pass the required examinations! While, on the other hand, out of 24 applicants from the College of Physicians and Surgeons of Baltimore, 8, or one third, failed; out of 16 from the University of Maryland, 5, or five-sixteenths failed; out of 7 from Jefferson Medical College of Philadelphia, 3, or three-sevenths, failed; and of the 3 from Howard University of Washington (colored physicians), all were rejected. Of course, this may be all right, but it would be hard to convince those who know anything of the relative merits of the above schools that the inferior graduates always come from schools located outside of Virginia, and that the graduates of the Medical College of Virginia are better educated men than those coming from first-class schools farther north."

Overcrowded.—The number of physicians who have located in Memphis during the past two years is out of all proportion to the increase in population. A few have remained with us, others could not stand the strain, and have sought other fields, while still others are coming in. —*Mississippi Valley Medical Monthly.*

A Bill to Regulate the Practice of Medicine in Rhode Island is before the Legislature.

The Medical Politics of Baltimore and the International Congress.—The Baltimore correspondent of the *Cleveland Medical Gazette* writes to that journal: "The meeting of the International Congress, which occurs next fall at Washington, D. C., is discussed somewhat, but there is not much excitement or even interest concerning it. The profession here is pretty well divided into two factions: 'The Maryland University' faction, made up of those directly and indirectly connected with the school and their friends, and 'The College of Physicians and Surgeons' faction, made up in the same way. When the first committee apportioned the positions in the sections, etc., of the Congress, 21 were given to Baltimore. Three of these were given to one man, thus making 19 men selected. Of these 19, 3 were from the Johns Hopkins University, 9 from the faculty of the Maryland University, and the other 5 among the friends of the University. Not one of the 9 was in any way connected with the College of Physicians and Surgeons, nor friendly to it. This, of course, was so plainly an intentional insult to the College faction that they resented it and joined the opposition party, which was so successful at New Orleans, in 1885, in destroying the work of the first committee. . . The new committee allowed Baltimore but 7 positions, instead of 21, which were given to 6 men. Four of these are of the College faction, 2 are not."

The Southwestern Medical Gazette is the title of a new monthly journal published at Louisville, Ky., and edited by Drs. M. F. Coomes and J. B. Marvin. The first number is excellently made up, and contains a large amount of interesting matter.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PRACTICE.

Stated Meeting, January 18, 1887.

ALFRED L. LOOMIS, M.D., LL.D., CHAIRMAN.

DR. E. DARWIN HUDSON, JR., was elected Chairman, and Dr. R. C. M. Page Secretary, for the ensuing year.

DR. J. WEST ROOSEVELT then read a paper (see page 210) entitled

A SHORT ACCOUNT OF OUR PRESENT KNOWLEDGE OF BERIBERI, WITH OBSERVATIONS ON CASES RECENTLY IN BELLEVUE HOSPITAL.

DR. E. C. SEGUIN reported three cases which he had seen in private practice. He had also had opportunity to see one of Dr. Roosevelt's cases in Bellevue, when he made an electrical examination; but it was too early in the period of paralysis to obtain any indication of the reaction of degeneration, and the quantitative reduction might be explained by an objector on the basis of being produced by the œdema. In one of his private cases there were areas of œdema. He thought that there was a strong resemblance in his three cases to alcohol multiple neuritis, and therefore that the term multiple neuritis as applied to beriberi was not inappropriate.

DR. VINEBERG, while a resident in the Sandwich Islands, in 1881, met with the strange affection, and studied it as closely as he was able to do without the aid of books, microscope, and other apparatus.

The more prominent features of the endemic, which he witnessed on three sugar plantations, were weakness and vague pains in the legs, without atrophy or loss of tactile sensibility, but very painful when grasped firmly. The muscles felt normal. The functions of the economy seemed to be normal. On one plantation several Chinamen suddenly dropped down in the field saying that they had lost power in the legs. Within a week fifteen of the sixty Chinese coolies on the plantation were stricken down with the malady. The patients walked with their legs wide apart, and not unlike a tabetic when paralysis is beginning to show itself. The reflexes were normal. Pain, at first, was referred to the region of the knees, and afterward vaguely to the thighs and legs, but not infrequently to the calves alone. Pricking sensations were felt in the legs. No evidence could be obtained that the spine was affected. There was no paralysis of the sphincters, and control over the rectum and bladder was lost in only a few fatal cases a few days before death. The appetite was good, tongue clear or slightly furred, bowels usually costive, the pulse frequent, the urine of normal color and free from sediment, and contained neither albumen nor sugar. Heart, lungs, and liver normal on physical examination. Judging from touch (thermometers being broken) there was no elevation of bodily temperature, except in a few fatal cases just before death. There were no cerebral symptoms, except muttering delirium in some of the fatal cases a short time before death, and in one in which there was "paranoia."

The sudden onset was not invariable. In many cases prodromal pains in the legs and gastric disturbances were present. In several cases the paralysis of the lower extremities was complete at the beginning, and many of these were the first to recover. Œdema of the legs was present in not more than five per cent. of the cases; in none did it become general. In all the cases attended by œdema there was valvular disease of the heart that seemed to have had an existence prior to the paralysis.

Hemorrhages, swollen gums, or other symptoms of scurvy were not observed in a single case.

Of the three hundred and fifty Chinese coolies employed on the three plantations fully one hundred were attacked. Fully fifty per cent. recovered; about thirty per cent. proved fatal, and the remainder passed into a chronic state. Recovery took place most frequently in from three to four weeks, and was liable to be interrupted by relapses of three to four days' duration. In the fatal cases death occurred in from three to four weeks after the onset, and seemed to be due to a rather rapid extension of the paralysis, which finally involved the muscles of respiration, the patient dying asphyxiated. In the chronic cases, beyond a weakness in the lower extremities, the patients exhibited no evidences of ill-health.

In his opinion the endemic was due to the effect of improper food upon a constitution deteriorated by overcrowding, masturbation, and other perverted sexual habits. Opium-smoking did not play any important rôle, because only a few dare-devils ran the risk of the severe penalty imposed by the laws of the islands. The overcrowding has reference to sleeping apartments, where the Chinamen slept upon two rows of shelves. The improper food consisted principally of pea-nut oil, tainted fish, sausage, and pork in an advanced stage of decomposition. Dr. Vineberg excludes contagion and malarial poison as etiological factors.

The treatment that seemed most efficacious consisted of rest, good, nourishing food, into which fresh vegetables entered, and more commodious and comfortable sleeping apartments.

At the Honolulu Hospital, where, in addition to the above, galvanism and faradism were used, a larger percentage of cases of recovery occurred.

There were several Chinese physicians in the district, but their abominable mixtures and free acupunctures of the sites of pain did not seem to be of any more service than Dr. Vineberg's plan of treatment based upon general principles.

DR. C. L. DANA had had an opportunity to see the cases described by Dr. Roosevelt, and did not find any history of paralysis or multiple neuritis until the very latest stages of the trouble; so to speak of the disease as an endemic multiple neuritis was not applicable to the cases seen in Bellevue. To him the cases looked more like those of paralysis following infective diseases. He made an examination subsequent to that made by Dr. Seguin, and then found the typical reaction of degeneration. It had been stated that the typical reaction of degeneration did not occur in multiple neuritis, although it is sometimes present. We also obtained other reactions not belonging to multiple neuritis. Some of the French writers were positive that only the wet form was true beriberi, while the dry variety was due to some other cause. Four different observers had discovered microorganisms, and it seemed to him that there was considerable probablity that the disease was due to some such specific cause.

DR. TAYLOR, of Japan, on invitation, participated in the discussion and spoke of the disease as he had seen it in that country. In the first place, it was restricted to localities, and its occurrence in these regions only was well marked. Thus a change of locality became of prime importance to the patient suffering from beriberi, and if not more than five or six miles, was of very much benefit. Upon an island at the mouth of a certain river beriberi had never been seen primarily, hence many were sent to that locality when they recovered. In the mountains, also ten or fifteen miles away, many might recover. But, according to his experience, if the force of the circulation was very much reduced, patients should not be moved; for the exertion incident to it was liable to be followed by paralysis of the circulatory apparatus, which might terminate fatally within half an hour.

With regard to diet, it had been his observation that with an increase of wheat and decrease of rice there was a decrease of beriberi. On this plan the occurrence of beriberi in the British navy had been very much diminished.

Concerning anæmia, his clinical experience had led him to believe that it was not a prominent symptom. In one hundred and thirty tabulated cases in which he had counted the red blood-globules, he did not find any diminution in their number, and he had come to believe that when anæmia was marked some complication was present.

As to muscular paralysis, he had not tested it with electricity, but had done it by asking the patient to raise himself upon his toes, and he had found that when beriberi was present this could not be done as when in health. Also, when about to sit, the patients would lower themselves to a certain point and then go down in a lump. In almost all cases of beriberi there was more or less of muscular paralysis, and in some cases it was decidedly marked.

Dr. Roosevelt, in closing the discussion, said he regarded it as a misfortune that the disease should be called multiple neuritis, and also that it should be looked upon as an affection due to any one kind of food. The fact should not be overlooked that while it has occurred among those who have subsisted on certain types of food, nevertheless it attacks people who have been living on all kinds of food, and have been surrounded by all that tends to make people physically comfortable.

He regarded it as particularly unfortunate to compare the disease with ordinary alcohol neuritis.

With regard to the presence of a micro-organism, although a number of observers claimed to have found one, it must not be forgotten that it was of the utmost importance, before accepting any report in this direction, to know who the man was, what his work was, what his method of investigation and technique were, and to those must be added the results of inoculation. Until all that had been done, the theory that the disease was due to a micro-organism was a subject of great doubt.

The Section then adjourned.

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY OF THE CITY OF NEW YORK.

Stated Meeting, January 19, 1887.

A. R. Robinson, M.D., President, in the Chair.

Dr. R. C. M. Page introduced the topic of discussion for the evening, viz. :

THE ADMINISTRATION OF QUININE IN THE TREATMENT OF BRONCHO-PNEUMONIA IN CHILDREN.

Referring to his own experience he stated: "I have come to the conclusion not to use quinine with children, for the reason that it is difficult to get them to retain it in their stomachs. In the first place, you have to fight with them to get them to take it. I have never discovered a vehicle in which quinine could be so disguised that children would not know it, and when they take it they are almost sure to vomit it. I remember an instance when a child, after taking quinine, went into convulsions. I think that antipyrin, in a little water, controls the fever of pneumonia, or any other disease, better than quinine.

"In a paper read last night at the Academy by Dr. Putnam Jacobi, it was claimed that quinine in moderate doses would increase the diastole of the heart, and thus tend to relieve congestion of the lung by drawing the blood from the lung; that in this way it stimulated the system and was a better drug than a systolic stimulant which increased the systole and drove the blood to the lung. In ten-grain doses it was contended that quinine is a very good drug in pneumonia in children, but that as an antipyretic it was a failure."

Dr. M. Blumenthal said: "I have given quinine to children in certain stages of pneumonia when they needed a stimulant, and though I have found the difficulty to which Dr. Page alluded, that they take it with great difficulty and vomit it, I do not think I have had more trouble in that way than with any other medicine. I usually give it in extract of taraxacum, dissolved so as to be taken with a teaspoon. I have not been in the habit of giving children large doses—small doses, often repeated, are my preference, and I have been pleased with its effects. I never give quinine in the first inflammatory period of the disease. I give it as a nerve tonic. To reduce the fever I produce free perspiration. I have not tried antipyrin in children's diseases. The general effect of quinine is different in children and adults."

Dr. Dessau said: "I have used quinine for pneumonia, but not as an antipyretic. In croupous pneumonia if I gave an antipyretic it would be to reduce the temperature, and if the temperature does not rise above 104° I do not trouble myself about reducing it. If it rises above that point I administer it to a child of two years of age, say from three to five grains repeated every hour for four doses. I have not yet given it to a child under two years. I have given it to older children in larger doses; to a child of nine years, ten grains, with the effect of reducing the temperature very markedly. I have used quinine in broncho-pneumonia in children to support strength and as a general tonic. In regard to any antipyretic cutting pneumonia short, especially croupous pneumonia, I do not believe it does. I believe that pneumonia is itself a disease, and all we need to do is to treat it on the expectant plan; and, if the fever rises too high, endangering the muscular fibres of the heart, keep the temperature within bounds. Antipyrin is the best antipyretic we have yet had. I have not used cold water as an antipyretic, as the accounts given of it have not been encouraging."

Dr. J. Lewis Smith said: "The paper read by Dr. Putnam Jacobi was in relation to the disease in childhood and infancy, and referred largely to cases under the age of three years.

"In my practice I have found it very difficult to administer quinine to infants or children on account of the vomiting which it is likely to produce. I have given it in various vehicles, and syrup of wild cherry bark seems to me to cover the taste best and prevent vomiting. As to the benefit to be derived from quinine, I think that it is more generally used in bronchial pneumonia, as well as in croupous pneumonia, than any other one agent, and there are physiological reasons which justify its use. The opinion has been expressed by some observers that it does, to some extent, retard cell-migration. If it is administered in a large dose, in the commencement of pneumonia, it may diminish the amount of exudation. I am inclined to think it does; and when I give it to a child with bronchial or with croupous pneumonia I give it in pretty decided doses for two or three days, that is, during the active period of the disease. This I think obtains better results than the administration of it in smaller doses. I believe it has a tendency to diminish the frequency of the pulse. As regards giving up its use for the remedies that have so recently attracted attention, I should not do it. From my experience with antipyrin I hesitate to use it. I think there is something in antipyrin having a depressing effect, and, although it may reduce the temperature, the result in the end seems to me to be not so favorable as the old treatment by the use of quinine and a nutritious diet."

Dr. Smith, on being asked what he considers the effect of quinine on the heart, whether stimulant or depressant, said: "I merely follow authorities on that question. In moderate doses I think it is a tonic and increases the systolic action. In large doses it acts differently upon the heart. There is a difference of opinion about that."

Dr. C. S. Wood said: "In regard to the use of quinine with children, I think special attention should be paid to the time of using it, if it be used at all. I used it formerly much more than I do now. Almost any dose, if it does not produce vomiting, appears to me to do them more harm than good, owing to the row they make

about taking it. During the early stages of the disease I do not think that quinine is called for, but antipyretics of various kinds may be used, and what I have mainly used is aconite in small doses. The over-distended heart is relieved by the very process of reducing its action. If that is not sufficient I believe in wrapping a wet cloth around the chest and body of the child, changing it frequently, and perhaps keeping it on for the first two or three days. When the acute symptoms have subsided, if we can administer quinine without a struggle on the part of the child, I admit that it is valuable. I believe, however, that a small dose of strychnine—from $\frac{1}{120}$ to $\frac{1}{60}$ of a grain, according to age, for children under three years—answers equally well, never disagrees with them, and can be given in one or two drops of liquid. I differ, perhaps, from many others with regard to the nature of the disease, and on that account may have biased views as to treatment. In my opinion it is not a specific disease, or one that is dependent upon the existence of a certain microbe. I believe the microbe to be the result of the disease in croupous pneumonia, and not the disease the result of a micro-organism. My success in the treatment of the disease, from that stand-point, has been as good as the average."

Dr. A. M. Jacobus said: "I have given quinine to children, but never in large doses, as they seem to me to have an unfavorable effect. I have given generally from one to two grains four times a day, more as a heart tonic than anything else. I believe it steadies the pulse. Since last summer I have used antipyrin with a high temperature, but not in large doses. From experience with adults I believe it prevents inflammation and that it lessens pain. I use both quinine and antipyrin, a little of each alternately."

Dr. J. H. Fruitnight said: "In the catarrhal pneumonia of infancy I never use quinine as an antipyretic—always as a tonic. In croupous pneumonia in adults or children, before the introduction of antipyrin, I always used quinine as an antipyretic. In broncho-pneumonia of infancy, in the early stages, I withhold quinine. If the temperature be high I use aconite. In catarrhal pneumonia I administer quinine as a tonic. The dose I give is divided to equal ten grains in twenty-four hours. I have given it in various vehicles, but since Dr. Smith suggested to me, some time ago, the use of wild cherry syrup, I find less trouble with that than with any other preparation. Most children retain it, and when there is any difficulty I instruct the nurse to give very small doses, increasing them gradually until the stomach assumes a tolerance of the mixture, and in that way I secure control of the symptoms of nausea and vomiting. As regards the effect of large doses of quinine my opinion is that it is a depressant, and I would never give a large dose to a child—never more than five grains at one dose. As regards the cold-water treatment, I have never resorted to it, but I have recently treated a child with antipyrin with good effect. Antifebrin I have never used."

Dr. S. N. Leo said: "My experience accords generally with that of Dr. Fruitnight. I have had occasion to administer quinine in both catarrhal and croupous pneumonia to very young children, and have been permitted to administer it in the form of rectal suppositories, which, I think, is an excellent plan of medication. I would also suggest that in compounding a prescription of quinine, if you take some powdered licorice and mix it with sulphate or bisulphate, add a little common salt, and beat it well up in the mortar, and afterward add a few drops of any alcoholic mixture, then mix with wild cherry, you obtain a most excellent compound. I think great care should be exercised in administering quinine to children in either form of pneumonia, and especially if they have had rheumatism we ought to be certain that there are no remnants of endocarditis, as then quinine seems to be a dangerous remedy, even in small doses. I recall some years ago a case in which I made an autopsy, where the child died, in my opinion, from an over-stimulation of the heart, due to the administration of quinine."

Dr. Peck asked how old the child was and how large the dose of quinine.

Dr. Leo: "I think the child was between four and five years. The amount of quinine administered was, I think, something like four grains every three hours, and it had been taken for quite a long time."

Dr. E. S. Peck said that he desired to contribute this statement, that the administration of quinia-sulphate in the doses just mentioned had been attended by injury to the retina of the eye, the medical attendant being ignorant of its possible extent, on account of the youth of the patient and the severity of the pneumonia. He once treated with strychnia injections a child aged four, who had taken six doses of quinia of three grains each, and there was no mistake about the retinal amblyopia. Fortunately complete vision was restored. The dangerous effect of large doses of quinia upon the acoustic nerve should be impressed upon every practitioner.

Dr. W. M. McLaury said: "In the treatment of broncho-pneumonia in children I rely very much on antipyrin to reduce the temperature, and in administering it to children I always use it in the form of suppository capsules; from two to ten grains, according to age and condition. I have never found any but good results from its use. I very rarely give quinine in the case of a continued fever, whether from disease of the lungs or general febrile condition. I rely mainly upon spirit of nitre and aconite to control the febrile symptoms. Antipyrin, however, has served me so well that I seldom fail to use it, giving it in doses from two and one-half to twenty grains, according to circumstances. I have given ten grains to children five years of age, and I generally repeat the dose within two hours if an abatement of the febrile symptoms has not taken place."

Dr. Baruch said: "I think that by making a sufferer of croupous pneumonia comfortable, and by giving an ample supply of food, we will accomplish more than by medicines. I have given no medicine in this disease within the last five years. The temperature in croupous pneumonia is, I think, of very little significance. Here we have an over-distended heart. Quinine is not intended and cannot be expected to overcome that. I think that by relieving the pulmonary congestion we can do more toward relieving the heart-weakness than by any other means. Grown persons I would not hesitate to bleed for this so-called heart-failure. For that reason I rarely give quinine. The rectal administration of quinine I regard as absolutely useless. I have always found the rectum not to be depended upon."

After some discussion as to the efficacy of the rectal administration of quinine, the President,

Dr. A. R. Robinson said: "I think, in judging of the value of any remedy in comparison with that of other remedies, we require to study the cause of the disease and the causes of death. Now, the cause of broncho-pneumonia is almost exclusively a bronchitis. It is very rarely that the agent producing the bronchitis produces the pneumonia at the same time. The bronchial secretion causes a falling in of the cell-walls of the vesicles, producing a change in the circulation. If the right side of the heart is weak, you very soon get œdema. The retained secretion, irritating the cells, produces the bronchial pneumonia. In the commencement we get very few nodules, but the trouble is that the number increases very rapidly, and we soon find a large area of consolidation. If you get a fair area affected, you have the danger of death from high temperature; consequently you have to treat for the general nutrition of the child; then the treatment for the fever and the treatment as regards air, if they suffer from respiration. If, therefore, it can be shown that quinine will be a benefit in the bronchitis, that it will build up the child, strengthen the respiratory muscles, tone up the blood-vessels, reduce the temperature

or strengthen the heart, it would be indicated, provided it will do no great harm in other directions. My experience of it has been that it has not been borne by children, and does not reduce the temperature, but, when retained, it probably tones up the walls of the blood-vessels. For that reason I would not use it, because we have better agents. I think the disadvantages are so much greater than the advantages that it is contraindicated in the majority of cases."

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE SURGICAL TREATMENT OF HYDATIDS OF THE LIVER—SANITARY IMPROVEMENTS AT THE HOUSES OF PARLIAMENT—UNQUALIFIED ASSISTANTS—ANOTHER FAITH-HEALER.

LONDON, January 31, 1887.

THE last meeting of the Medical and Chirurgical Society was entirely occupied in discussing the treatment of hydatids of the liver. Mr. Barwell opened the discussion by reading a paper on the subject, in which he proposed a modification of the treatment by incision. He recommended that puncture, with a small trocar, should always be primarily employed, but where this failed he advocated the making of a free opening, to be kept open some time. In the paper read last Tuesday he advocated the employment of "a two-stage method." The abdominal walls were to be first incised, and the cyst or its surroundings stitched to them. After a few days' delay the cyst was then to be opened. Mr. Warrington Haward thought the method dangerous, as fluid might escape when stitches were inserted into the parent cyst. He preferred the use of caustic potash to form a fistula leading down to the cyst, and then free incision of the latter. Mr. Howard Marsh said he had successfully employed Mr. Barwell's method on a large cyst. Mr. Harrison Cripps narrated a case in which he had made an exploratory incision, and, finding a suppurating hydatid, had enucleated it along with its capsule. A large cavity was left in the liver, and into this a second tumor was seen bulging, and was removed. Sir Dyce Duckworth thought he had seen good results from all these surgical methods. Mr. Walsham observed that even tapping had its dangers. Cases of sudden death had occurred in which it had been suggested that a vein might have been punctured and the hydatid fluid introduced into the circulation. He had not himself had any occasion to perform any preliminary operation of stitching the cyst or its surroundings to the abdominal walls. After securing the cyst in a safe place by forceps, he emptied it at once. He then syringed it out with carbolized water, and after filling it with iodoform, inserted a drainage tube. Dr. Angel Money mentioned a case in which, during the operation of puncture, a daughter-cyst entered a vein and lodged in the right auricle, causing sudden death. Mr. Pearce Gould said he supposed no one would attempt such an operation as Mr. Barwell advocated while simpler methods, such as puncture, were available. If a further operation than puncture were required, he advocated free incision, and related two cases in detail. He would, he said, first tap with an aspirateur, then pull out the half-collapsed cyst, stitch it to the abdominal walls, and evacuate the contents. Mr. Henry Morris said that, as to stitching the cyst to the abdominal walls before opening it, he saw no objection to Mr. Barwell's plan, but little in its favor. He considered it important not to interfere with the parent cyst in any way, to take out as many daughter-cysts as possible, and refrain from antiseptic injections. He had seen delirium produced by iodoform. Mr. Barwell, in his reply, also condemned iodoform as dangerous. Potassa fusa treatment he considered tedious and painful. He remarked that the discussion had shown him that other surgeons had used the plan he advised, but he had not previously been aware of this.

It augurs well for future sanitary legislation that our legislators have set their own house in order. The sewerage of the Houses of Parliament has just been rearranged at a cost of about fifty-five thousand dollars. The old drains were of brick, far too roomy, laid so that the fall was insufficient, and sewer air regurgitated into the Houses of Parliament. They have been replaced by iron pipes of moderate dimensions, laid so as to give a greater fall, and freely ventilated throughout. The ground at Westminster lies so low that the outlet of the new system of sewers is several feet below the low-level main sewer. The difficulty thus arising has been got over by employing Shone's pneumatic system. One or more gas-engines are used to compress air, and the compressed air is admitted into a pneumatic ejector and raises the sewage some twelve feet. The apparatus acts automatically so long as the supply of compressed air is kept up, the ejector emptying itself as soon as it is filled to a certain level. The trials which have been made with the apparatus show that it answers the expectations which had been raised of it, and it is now in full working order.

Considerable discussion has taken place lately on the subject of unqualified assistants. Lord Beaconsfield defined critics as "authors who have failed in their profession." Similarly, unqualified assistants are, as a rule, students who have failed to qualify as medical men—either from want of brains, or, in not a few cases, from want of money. There is among them a scanty sprinkling of men who have never been students at all, but have picked up a smattering of physic, either in a doctor's surgery or behind the counter in a druggist's shop. As formerly, the outcry against unqualified assistants has raised up in their defence a host of friends ready to testify to their good qualities. Not a few aver that they are, as a class, immeasurably superior to the average qualified assistant—both in practical knowledge and in acquaintance with the details of practice. That they should be better conversant with the petty routine of practice no one ought to be surprised at. The unqualified assistant remains such to the end of his career in ninety-nine cases out of a hundred, and is usually a "chronic" to begin with. The qualified man who seeks an assistancy is usually raw as to practice, though brimful (in his own estimation) with science. His object in seeking an assistancy is usually to get a little experience of actual practice before embarking in one on his own account. A few qualified men remain, from want of money, for years in the subordinate position of assistants; but the natural ambition of all is to have, sooner or later, their own practice. In England, unqualified assistants are very largely employed, though, perhaps, not to so large an extent as a generation ago. They are cheaper than qualified ones, and being without qualification, there is no danger of their setting up in opposition to their principals. Their being older is also a recommendation with patients. The unqualified assistant is often a beardless youth, full of airs as to his own importance, but frequently considerably nonplussed on being summoned to a simple case for which his college course has not prepared him. To such, measles is, at first, a *bête noir*, and the other disorders of childhood all-bewildering. As to diseases of children, indeed, most newly qualified men, whether assistants or not, soon get befogged. A case came under my notice not very long ago in which a not undistinguished youthful graduate was sent for to see an infant suffering from bronchitic catarrh. He looked at the little sufferer, and remarking that it was too young to take medicine, sagely told its mother she could do nothing but keep it warm. He then departed, leaving his reputation behind him—never to be resuscitated, so far as regards his knowledge of in-

fantile disorders, in the eyes of that particular mother. She sent for a neighboring olde. practitioner, who, although not a graduate, gave satisfaction to the family, and gained several fees for himself.

Another faith-healer has lately made his appearance here. The gentleman in question is Mr. George Milner Stephen, and hails from Australia. He is a cousin of the eminent legal luminary, Sir J. Fitzjames Stephen. Mr. Milner Stephen is good enough to inform the public that he has visited America, and performed many wonderful cures there, as in Australia. Perchance, therefore, some of your readers may know something of his career. His course here is likely to speedily terminate with ignominy. One of the daily papers has sent a special commissioner to interview Mr. Stephen and take some test cases for him to operate on. Strange to say, though, in every one of these cases did the faith-healer discover some obstacle to the successful exercise of his powers. One case was too bad; another was of too long standing. Another had been treated by other doctors in an antipathetic manner, or the patient's attitude of mind was inimical to a cure. Another objection raised was that many applications of the power would be necessary, and as the test-patients did not pay, naturally Mr. Stephen did not desire that they should make repeated visits. The conclusion drawn by the interviewer was that Mr. Stephen was an unmitigated impostor. He will probably soon vanish from London society, and the little stir created by his advent as speedily subside.

THE CHOLERA IN JAPAN.

To the Editor of The Medical Record.

Sir: Japan in, modern times, has suffered more severely from the scourge of Asiatic cholera than any other country within the belt of the temperate zone. Since I came here, in 1859, when the country was first opened to the Western world, there have been two distinct periods of long epidemic prevalence of the disease.

The first, in 1860, was fearful in its death-rate, and continued to destroy thousands during successive summers, till about the year 1867, when it died out.

As there was no systematic record of disease and death-rate at this time, the sum total, or even an approximation to power of the scourge, can be little more than conjectured. My own recollections of the first two years, especially, of this period are very vivid. Hundreds, and it is not too much to say thousands, died without even native medical aid, and in the cities near the sea the water was often their burial-place.

In 1877, while acting as Sanitary Officer of the port and city of Yokohama, I recognized the first cases of the return of the disease here, which had been, as far as could be ascertained in the absence of any quarantine regulations, imported from China. In virtue of my office I was then charged with the preliminaries of applying, for the first time in the history of this country, the principles of modern sanitary science to an arrest or control, as far as possible, of cholera.

Notwithstanding the utmost liberality on the part of the government, and the intelligence and untiring efforts of the native medical men in developing and perfecting sanitary measures according to the best known methods in the Western world, it has not succeeded in forcing the disease from its stronghold upon the country.

In 1879 there were over ninety thousand cases, and the statistical returns of the past year, just issued, mark fearful total of 154,373 cases, and 101,695 deaths.

Detailed and exhaustive reports of this year's sanitary work are now in course of preparation by the Central Sanitary Board, in which the wonderful progress of this people in this important branch of science will be strikingly brought out. I would here say in advance that the most important feature of the sanitary system carried out in this country, quite eclipsing that adopted by the highly civilized Western world, is the cremation of *all* dead from cholera.

Extensive appliances for the purpose are constructed on scientific principles in different parts of the Empire. In the city of Kyoto these appliances are on such a large scale that five hundred cremations can be made in twenty-four hours. Yours truly,

D. B. Simmons, M.D.

Yokohama, January 8, 1887.

"THE COUNTRY DOCTOR AND HARD THINKING."

To the Editor of The Medical Record.

Sir: I have read with great interest the article in your journal entitled, "The Country Doctor, and Hard Thinking," and fully agree with "Rusticus" in his letter in your issue of January 17, 1887, and would like to relate some of my own experiences. Seven years ago, one dark stormy night, I was called to go eight miles from my office to see a patient, and asked to come quickly. After driving about five miles I found the road impassable. I left my team in an old unused shed by the roadside, covering my horse well with blankets, and travelled the remainder of the way across ponds and fields on foot, arrived at the house all wet and exhausted, administered to the wants of my patient, who was suffering severely (and would have died without assistance), waited until she was resting quietly, and then returned home in the same manner.

One day during a terrible snow-storm, when the drifts were several feet deep, I attempted to go (by way of an old road) to see an acute case of pneumonia (of which we have no small amount in Massachusetts). The result was that my team was completely stuck in the snow. I unhitched my horse, beat a path with hands and feet for him, and led him to the main road, then went back and drew out my sleigh myself. I had just arranged my team when my coadjutor came along and reported that he had worked all day to get five miles from home through the drifts and cross-roads.

I could repeat hundreds of these instances; but there is one point more: After driving sometimes several miles, the country doctor often comes in contact with cases that even a specialist would shrink from, but he has no one at hand for counsel, is without suitable instruments or medicines, and the patient is too poor to send to the city hospital. Well, he must be relieved somehow, and the doctor, fully knowing what is wanted but unable to obtain it, must use all his brain-forces to meet the emergency, *and he will do it too*, and rise out of the trouble triumphant. Now, let one of your very fashionably dressed M.D.'s from the city come here, and I will loan him my office from now until spring time, and if he will attend well to my patients, I am confident he will be converted, begin to realize what a country doctor's life is, and what his medical acquirements must be. We have at the present time nearly three feet of snow on the ground and drifts by the wholesale.

Country Doctor.

THE DISPENSARY ABUSE.

To the Editor of The Medical Record.

Sir: The editorial in your issue of January 22d, on "The Present Condition of the Medical Problem," is a timely statement.

The evils of indiscriminate medical charity are not lessened as they should be, but the profession is more fully aroused to this abuse than formerly.

The reorganization of the Out-door Department at Bellevue is, indirectly, a help to the reform, as the classes are now used to supply the colleges with clinical material, and the advantages of the City as a centre of medical education are increased without adding to the thousands of people who receive gratuitous treatment.

It is not likely that the number of medical schools will be augmented, and the demand for clinical cases will not be greater than it was a few years ago, when rival institutions were striving to find injured and diseased persons suitable for exhibition to their classes as the best advertisement of their future courses of instruction.

Some new dispensaries have been opened, much against the expressed wishes of prominent medical men. This leads us to inquire whether it cannot be made the duty of the State Charities Aid Association, or of our local societies, to prevent the increase of eleemosynary institutions in districts already occupied.

A few of the dispensaries have continued to investigate the cases applying for relief, and as far as I have learned this has proved satisfactory. The physician himself must work to prevent whatever abuse comes under his own eye. If this be done, there will be an abatement of the evil and less necessity for public meetings and discussions.

That this is a subject of great importance is shown by the revival of interest in the provident dispensaries in England. Timothy Holmes, and others equally well-known, have spoken and written in favor of a more systematic application of medical charity.

Respectfully yours,

WALTER LESTER CARR.

36 WEST THIRTY-SECOND STREET,
January 28, 1887.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 6 to February 12, 1887.

FRYER, BLENCOWE E., Major and Surgeon. Ordered to Fort Lowell, Ariz. Terr. S. O. 29, A. G. O., February 4, 1887.

LORING, L. Y., Captain and Assistant Surgeon. Leave of absence still further extended three months on surgeon's certificate of disability. S. O. 29, A. G. O., February 4, 1887.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Leave of absence further extended one month. S. O. 29, A. G. O., February 4, 1887.

WOOD, LEONARD, First Lieutenant and Assistant Surgeon. Ordered to proceed to these headquarters, and report to Department Commander for temporary duty. S. O. 12, Department of Arizona, January 31, 1887.

HARRIS, H. S. T., First Lieutenant and Assistant Surgeon. Ordered from Fort Clark, Tex., to Fort Ringgold, Tex. S. O. 16, Department of Texas, January 31, 1887.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 12, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	3
Scarlet fever	48	10
Cerebro-spinal meningitis	3	3
Measles	349	47
Diphtheria	129	39
Small-pox	12	2
Yellow fever	0	0

CIMICIFUGA RACEMOSA IN THE TREATMENT OF CHOREA.—Dr. Hiram Corson, of Conshohocken, Pa., in an article on chorea and its treatment by cimicifuga racemosa (*Medical and Surgical Reporter*) says that he has used this drug with invariable success for over fifty years. He was led to give it a trial through its recommendation by Dr. Jesse Young, in a paper published in the *American Journal of the Medical Sciences*, in 1832. He thinks that Dr. Jesse Young was probably the first regular physician who ever used the black snake-root in chorea—at least the first who published an account of its use; for in a note by the editor, appended to the communication, he says: "We are not aware of the remedial powers of the black snake-root having been noticed by any writer on the materia medica, but Dr. Physick informed us, nearly ten years ago, that he had known the plant, given in doses of ten grains every two hours, prove successful in the treatment of chorea in several instances." From the day that Dr. Young's recommendation of cimicifuga met his eye, until the present, Dr. Corson has relied on the snake-root alone, "and in every case it has given speedy relief." In addition to believing it "almost if not quite a specific in chorea," the author also maintain that it is of signal benefit in "nervous persons" who are afflicted with insomnia. Again, Dr. Corson says, we have much talk about "nervous exhaustion," and the value of "strychnine and iron, and a little good whiskey, as tonics to build up the system," and arsenic is the universal favorite in chorea; but he feels assured that all of them combined have not half the value of the infusion or fluid extract of black snake-root, a plant that is accessible to every Pennsylvanian doctor, as it grows on almost every wooded hillside in that State; and yet but few physicians are acquainted with it—cannot point it out, though it towers above nearly all the other plants of the forest. "In every county in the State," he presumes, "it can be found; any mother can prepare and administer it; and were this done early in the cases of chorea, which are found in every township in the land, physicians would not be mortified, and the inefficiency of our profession exhibited before the public by the appearances on our streets of young persons helpless in limbs and contorted in features by this disease of the nervous system."

FLUID EXTRACT OF CORN SILK IN THE TREATMENT OF CYSTITIS.—Dr. Rush M. Brown reports good results from the combined local and internal use of corn silk in catarrhal troubles of the bladder (*The Medical Age*). He injects into that organ half a teacupful of tepid water, to which has been added a teaspoonful of the fluid extract of corn silk. At the same time ten drops of the medicine are to be taken internally three times a day. The results in a number of cases were surprisingly good.

HYSTERICAL ANURIA.—The Paris correspondent of the *New Orleans Medical and Surgical Journal*, January, 1877, writes as follows concerning this condition: "In an important work by Dr. Rossoni, on hysterical anuria accompanied by secretion of urine by the stomach, he says that anuria is not a rare symptom in hysteria. This anuria results from a physiological change of the functions of the human organism, the nature of which has not been ascertained. With hysterical patients having anuria, the stomach may be the receptacle of a more or less abundant secretion of a liquid presenting all the physical and chemical properties of urine. Urinary secretion of the stomach may cease, and yet not be carried on by the kidneys. Complete anuria may last for two months. Pilocarpine may, in some cases, hasten the resumption of renal functions; with some hysterical patients pilocarpine occasions, in the salivary glands, the secretion of a liquid presenting the same chemical properties as urine. Urea artificially introduced into the circulatory system, in cases of hysterical anuria where there is no secretion of urine by the stomach, occasions uræmic symptoms. On the contrary, urea may, with impunity, be introduced in doses of sixteen grammes in case of hysterical patients, subject to vomiting urine. There is no analogy between hysterical anuria and uræmia in nephritis, or from the absence of the kidneys after nephrotomy, or from ligature of the ureters.

Locomotor Ataxia in Children.—Several supposed cases of this affection in children have been from time to time reported, but most of them were really cases of the hereditary ataxia of Friedreich, an affection resembling in many particulars *sclérose en plaques*. Remak has, however, reported two cases in the *Berliner Klinische Wochenschrift* of apparently genuine tabes dorsalis. One occurred in a girl twelve years of age, and the other in a boy of fourteen years of age.

Diabetes in Childhood.—Dr. Albert F. Fuchs writes that he has had under observation a case of diabetes in a boy four years and eleven months of age. One sample of the urine showed a trifle over seven per cent. of sugar. The total amount of sugar excreted in the twenty-four hours could not be determined, as the child died in coma on the third day after first coming under observation.

A Russian Centenarian.—On September 6th was celebrated in St. Petersburg the birthday of Count Sergius Ouvaroff, who was born in 1786. As a youth he passed a number of years in Paris as secretary of the Russian legation, and from 1833 to 1851 he was Minister of Public Instruction in St. Petersburg, and was mainly instrumental in introducing the classical method of instruction in Russia. He published a number of works in Russian, German, and French.

Diagnosis and Treatment of Tumors of the Bladder.—Dr. Guyon made some remarks at the French Surgical Congress upon tumors of the bladder, claiming that exploratory incisions are not requisite for diagnostic purposes, but that the symptoms presented, together with a clinical and anatomical examination, were sufficient in the majority of cases (*Journal of Cutaneous and Genito-Urinary Diseases*, February, 1887). He compared the hæmaturia symptomatic of vesical neoplasm with that of kidney tumor, in which latter the signs of renal ballottement and symptomatic varicocele aid us. He then dwelt upon the exploration of the bladder per rectum, per vaginam, and by catheterization, and said that little information could be obtained from the latter mode of examination. A tumor of the bladder being discovered, it should be operated upon as soon as possible, unless all the walls of the organ are infiltrated with the disease. Malignant as well as benign tumors should be operated on, the fact being remembered that the malignant are almost always followed by a return of the disease, and that the benign usually get well. Benign tumors can occupy the bladder for a long time without causing the patient more annoyance than that caused by hæmaturia, etc. One should not hesitate to operate when in the presence of a complication such as cystitis, retention of urine, etc. The extirpation of the tumor, he believes, cannot be properly done except by the hypogastric incision.

Bed-Smothering.—A most pernicious habit, which is very prevalent among children, is that of sleeping with the head under the bed-covers. Sometimes children acquire this habit when young, on account of their "fear of the dark." Unwise parents often do their children a vast deal of harm by using the imaginary man in the dark as a means of frightening the little ones into obedience. Such children, when put to bed, nestle down under the covers as soon as the light is put out, and thus breathe over and over, during sleep, air which is contaminated by exhalations from both the skin and the lungs. Another cause for this injurious mode of sleeping is cold sleeping-rooms. The custom of sleeping in rooms in which there has been no fire for weeks or months, is a most pernicious one for many reasons, and this may fairly be included among the number of grave objections to the old-time custom. The temperature of such a room is often some degrees below freezing. Children, and even older people, sleeping in a cold bedroom, are often compelled to cover the head with the bed-covers to protect the nose and ears from freezing. Children who sleep in this way awake in the morning pale and languid, and present all the evidences of systemic poisoning. Such children do not develop properly. When they sleep with older persons, as is often the case, the evil is greatly increased by the greater degree of impurity of the air beneath the bed-clothing. Infants are not infrequently smothered to death by this means. Several cases of this sort have come under the personal observation of the writer. The habit of sleeping with the head thus covered is sometimes continued to adult life, and a vast deal of constitutional injury is thus done.—*The Pacific Record.*

A Cure for Neuralgia, which is highly praised, is given by Dr. H. G. Davis in the *Boston Medical and Surgical Journal*. It consists in administering the following:

℞. Tinct. cichon. co..... ℥ ij.
Tinct. nuc. vomic..... ℥ ss.
Morphiæ sulph..... gr. ij.
M. Sig: ℥ j. q. 3 h.

This amounts, as will be seen, to giving a tenth of a grain of morphine every three hours. Naturally it will relieve the pain, but it is hardly a safe remedy.

Opium-Smoking.—In an article in the *Indian Medical Gazette* Surgeon-General Moore defends the practice of opium-smoking, and maintains that it is not only not harmful, when indulged in moderately, but that it is even beneficial. The use of opium, he says, may be continued for years without the necessity of increasing the dose, and a moderate opium-smoker is no more likely to become an "opium fiend" than is the temperate user of alcohol to become a drunkard, and even among the confirmed abusers of the drug there are seen none of the distressing effects of alcoholic intoxication. The writer says that the members of the Anti-Opium Society, in their misplaced zeal, would take away from the poor an inexpensive source of enjoyment, a protection from disease, and an alleviation of their sufferings. But perhaps his strongest argument, and a very characteristic one, is that the Anti-Opium Society, if it succeeded in its objects, would diminish the revenue of India by seven or eight million pounds sterling.

Successful Removal of Entire Scapula for Osteo-Sarcoma.—At a recent meeting of the London Clinical Society, Mr. Charters Symonds reported a case of removal of entire scapula for osteo-sarcoma, two years having elapsed since the operation without any recurrence of the disease. (*Medical Press.*) Six months before admission the patient fell and bruised his shoulder, attending for a month the Croydon Hospital, where he was told he had ruptured a muscle. One month after the accident a swelling appeared, and from that time steadily advanced without pain. The inconvenience was due entirely to its size, the man being unable to do heavy work. When admitted he was healthy in other respects. To the dorsum of scapula was attached a tumor measuring nine to ten inches, and projecting five inches from the surface. It moved with the scapula, and did not appear quite to reach the glenoid cavity. The spine of the scapula could just be traced. On April 1, 1884, the whole bone was removed except the acromion and coracoid processes. The usual transverse and vertical incisions were made, one flap only being reflected at a time. First the minor flap was dissected off and the posterior border of the bone freed. Next the inferior angle was isolated, and then the anterior flap was reflected and the axillary border freed, the various muscles being divided. The deltoid and trapezius muscles were divided close to the spine of the scapula, and the superior border was freed. The growth was found to extend to the glenoid cavity, so after sawing off the acromion and coracoid processes, the capsule and the muscles covering it were severed. The whole mass was then raised from the

chest, and the serratus magnus divided. The subclavian was compressed during the operation, and all the large vessels seized by two pairs of forceps before being divided. In this way little blood was lost. The same evening the man had an unexplained attack of dyspnœa, which lasted twenty-four hours, and interfered with sleep. The temperature rose quickly, reaching its highest point, 103.6, on the fourth day, but instead of falling it passed into a hectic fever, which lasted until May 9th, and then suddenly ceased on the removal of the cause of suppuration, viz., the head of the humerus. Rapid recovery ensued. Another clinical feature of interest was œdema of the arm, without redness and with no special fever. This was attributed to thrombosis of the axillary vein, but as it disappeared within a few days of the removal of the head of the bone, some other explanation seemed called for. Mr. Symonds called attention to the fact that the continued suppuration seemed due entirely to the cartilage covering the head of the humerus. This structure was found in a suppurating state, and was being thrown off by granulating tissue, and the moment the entire surface was removed recovery began, and was so rapid that within a few days he was up and the parts nicely healed, the man gaining flesh within three weeks. The complication was attributed previously to traumatic fever, which determined suppuration in the wound, and that this, involving the joint structures, the cartilage acting like a foreign body maintained the suppuration. On these grounds Mr. Symonds said he now always carefully removed all cartilage in operations involving joints, for that while in many cases immediate union does occur, when the cartilage is left, an occasional result such as the present will happen. The man was shown to the society two and a half years after the operation, and had a useful arm. He could do much of the lighter work of his trade of a carpenter, being able to drive nails and screws and use a plane. He was able to earn a good living. The rhomboid muscle acted well, having obtained a partial attachment, so that the man could throw both shoulders back. He could rotate the shoulder and carry it backward and forward, but was unable to raise it from the side. The tumor was a hard osteo-sarcoma, having a basis composed largely of fibrous tissue.

The Treatment of Puerperal Sepsis.—Runge, of Dorpat, states that his late experience in the treatment of puerperal sepsis has taught him a manner of dealing with the affection that yields far better results than other methods. A strict *local* therapeusis is carried out. Rigid antisepsis of hands and instruments in conducting the labor is the best prophylactic. The vulva is cleansed at the beginning of labor, but no vaginal irrigation is used before, during, or after a normal labor, and in such uterine irrigation is held to be a *lapsus artis*. Lacerations are sutured if large, or dusted with iodoform if small. When fever sets in the cause is sought for, and if found in the genital apparatus he uses vaginal irrigations —temporary are preferred to permanent—and in cases of offensive lochia, uterine irrigation with a five per cent. carbolic acid solution. The latter is repeated once or twice, and during its use the vagina is protected by a stream of water. Further absorption of septic matter is in this way prevented. The object of general treatment is to raise and maintain the power of resistance of the system, to enable it to throw off the poison absorbed. To accomplish this purpose the most important vital functions of the organism must be maintained and regulated. These are sleep and digestion; and while these are preserved the system cannot yield to the disease. All measures that impair the ability to take food must be considered objectionable in puerperal sepsis. Experience shows that the resisting powers of the organism are best maintained when *alcohol in large doses* is combined with *tepid baths*. The first results observable under their use are ability to take plenty of nourishment and the setting in of sound sleep, especially in restless patients. Alcohol is exhibited in the form of Stokes' mixture: ℞. Cognac, aqua destil., āā 60.0; vitellus ovi unius; syr. simpl., 25.0, of which one to two tablespoonfuls are given every hour, and between these doses one to three tablespoonfuls of some strong wine. This is continued day and night until sound sleep ensues. To show the quantities taken he cites the instance of two patients, one of whom took, during the first twelve days, twelve bottles of port wine and 1,200 grammes of cognac; and the other, from the second to the ninth day, ten and a half bottles of port or Madeira, and two litres of cognac. But alcohol alone does not bring on a desire for food. This is accomplished by the simultaneous use of tepid baths. Refusal of food, increased somnolency, a frequent and weak pulse, a high and equal temperature, restlessness and delirium, are indications for a bath. Collapse, also imminent collapse, as indicated by unequal temperature and a flickering pulse, contraindicate a bath, while metastasis to the lungs and femoral thrombosis indicate great care in their use. The temperature of the bath should be 81° to 85° F., and in case of great somnolency one or two cold douches should be applied. It should not be extended beyond five to ten minutes, and at times a simple immersion is all that is admissible. He rarely begins with the baths before the third day, and gives one, two, and three baths a day. Under this treatment patients readily take food, and milk, eggs, meat broths, and meat, the latter finely cut or scraped, is freely given, and taken with relish. Castor-oil is at first used to relieve constipation, if present, and later on enemata are employed. Severe pain demands opium and ice to the hypogastrium, the ice being replaced by hydropathic compresses as the pain becomes less severe. After defervescence is complete the patient is for a long time kept on large doses of ergot. The general should be begun conjointly with the local treatment. In the lymphatic form of puerperal sepsis, characterized by tympanites, no great pain, frequent and feeble pulse, singultus, rare or absent vomiting, the puerperal peritonitis of authors, this line of treatment yields admirable results. It remains powerless in the form simulating perforative peritonitis or septic peritonitis after laparotomy, in which intense pain, enormous tympanites, and incessant vomiting are pronounced symptoms. Runge compares the present line of treatment with that of former years. The local treatment was what it is now, except that at one time voluminous irrigations were used for prophylactic purposes, but again quickly abandoned when it became apparent that the mortality rate was increased. The general treatment consisted then, as now, of alcohol, but it was given in small, inefficient doses, and only when grave symptoms arose. Large doses of quinia were given under the sway of Liebermeister's views, for the purpose of reducing temperature. They did not at all influence the course of the disease. Thanks to the labor of Fränzel, Unverricht, and Naunyn, the views as to the injuriousness of fever have been set aside. But quinia, salicylic acid, and the other antipyretics do not now exert as good influences on the course of the disease, but are positively injurious in puerperal sepsis by impairing and destroying the desire for food, and by covering up the real condition of the patient by their physiological symptoms when given in massive doses. The favorable influence on the heart's action and on the respiration, the action on the sensorium, the effect of maintaining and stimulating the desire for food, make the line of treatment now followed out stand out brightly before all others.—*Journal of the American Medical Association.*

HEART-STRAIN AND WEAK HEART.[1]

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

CERTAIN forms of cardiac incompetency, which I frequently meet with, have had for me, during the past few years, a special interest. I do not yet know the best term to apply to *all* these cases; in fact, I do not believe, as is already shown by the title given above, that they should *all* be classified in the same division. They offer, in my opinion, various symptoms, are not invariably due to the same causes, and present frequently somewhat different and more or less well-marked physical signs. Occasionally there are in reality no evident physical signs which reveal the condition of cardiac weakness. In the analysis of my cases I find, unfortunately, that in many particulars my histories are imperfect, and especially so from the standpoint where I now desire to study them. In one way, however, I believe this deficiency is desirable, rather than the contrary, for it shows precisely how the cases impressed me at the time notes were taken and the patients under observation. Inasmuch as when many of the facts were recorded I had no idea of utilizing them to support my present views, they are, it seems to me, freer from bias than they might have been under different circumstances. I regret very much to add that search made latterly among hospital and dispensary notes has been relatively of little use to me, since the histories do not often relate to cases of the kind I desire specially to describe, or, if they do, mention is usually omitted of the facts which are of special value, and which pertain either to etiology or symptoms of certain forms of cardiac disease.

Of course, I wish it to be understood, and particularly by those members of the Society who have devoted themselves to the careful and exact study of cardiac disorders, that I have probably nothing *new* to offer *to them*. They are already familiar with the subject of my story; it merely remains to be determined whether they and I have interpreted some interesting clinical facts in a similar or somewhat different manner. Many years ago, as all of you know, Da Costa[2] described what he called "irritable heart." This affection was first brought to his attention during the War of the Rebellion. Large numbers of soldiers were affected with it. It was seemingly brought on by long marches, fasts, exposure, mental anxiety, continued during many months. It was an affection characterized by dyspnœa, pain localized over the heart, palpitations, a frequent and sometimes irregular pulse. The heart was occasionally enlarged; frequently it was of normal size. The observations of Da Costa have been corroborated by several eminent writers; among others by W. C. McLean and by Fraentzel.[3] These authors found in soldiers cases of hypertrophy and dilatation accompanying symptoms of feeble and irritable heart, and resulting from long marches and the pressure of dress and accoutrements, or the hardships pertaining to army life in the field.

In 1865 Thomas B. Peacock directed attention to over-strain as a cause of heart diseases, and according to Leyden[4] was the *first* author who described these cases with precision. Special forms of cardiac disease were recognized by him among the workers in tin and copper mines.[5] In England, also, at a later period, Clifford Allbutt[6] pursued analogous investigations with respect to laborers in other vocations. It was remarked by him that forge-men, barge-men, etc., or those workers who made excessive and prolonged muscular exertion with their arms, were sufferers from cardiac hypertrophy and dilatation. About the same time as Allbutt, Myers observed diseases of the heart among soldiers, due to strain, etc. According to Dr. Morgan, who wrote an essay entitled "University Oars," being a critical inquiry into the after-health of the men who rowed in the Oxford and Cambridge boat-races from the year 1829 to 1869, based on the personal experience of the rowers themselves, *rowing*, unless permanently indulged in, does not cause organic disease of the heart. Undoubtedly in persons predisposed to irritable heart, or other functional cardiac disorder, *rowing* increases it (Da Costa).

At the time Allbutt published his communication on a subject related to that of my paper, little attention had been paid by English writers to the mechanical causes of heart disease. Nothing could be found among them, except here and there a vague statement, as in Hope, where he says that rowing sometimes gives heart trouble. In foreign authors, at the time referred to, little more could be gleaned. The interesting facts studied by Allbutt with much exactness, were, later on, graphically described by Fothergill.[7] The late Dr. Austin Flint, in an admirable chapter on "Functional Disorder of the Heart," already in his work on "Diseases of the Heart," and subsequently in the successive editions of his "Practice of Medicine," showed how mental emotions, the influence of the passions, the improper use of stimulants, might all ultimately produce organic cardiac disorder. Quain[8] also directs attention to the influence of the emotions and prolonged exertion in producing hypertrophy and dilation of the heart, and Seitz[9] has insisted upon the various local and general symptoms caused by cardiac over-strain. In an article entitled, "On the Dilatation and Hypertrophy of the Heart, which are not produced by Changes in the Valves," by Delafield,[10] many valuable facts bearing on this subject can be read. Finally, in the last number (October, 1886) of the *American Journal of the Medical Sciences*, there is a very complete and satisfactory summary of an article by Leyden, in the *Zeitschrift für Klinische Medicin*, previously mentioned, on "Diseases of the Heart resulting from Over-exertion." So far as my knowledge and reading extend, there are few, if any, studies elsewhere to be found which afford a more thorough presentation of this matter. Still there are some features connected with similar and analogous cases which have seemed to me somewhat different from those thus far dwelt upon, at least in a forcible manner, and these are the topics to which I ask your attention. In the hospital and dispensary work, and more particularly in the latter, which I have done for many years past,

there scarcely passes a week in which I do not see one or more cases of chronic heart disease brought on mainly by physical over-exertion, and usually of prolonged character. Of course these cases differ from each other in respect of the *stage* of disease when they come under observation. They are unlike, also, in many instances, because the heart is not always affected in a similar manner, without regard to the period of the affection. This may depend upon the nature of the pursuit of the individual, upon his habits of life, upon concomitant or previous diseases. A most important factor, in my opinion, is likewise *the individual himself*. We have no absolute means, so far as I am aware, of estimating the real strength of the heart as a vital organ, except through its power of resistance to certain depressing and altering agencies. We do not know, for example, in advance, and when it is a question of one man or another, whether or not the person who is under consideration possesses a heart which shall be strong to resist great and prolonged fatigue, exposure or want of rest, poor food, or bad hygienic surroundings, the inroads of acute or chronic disease, the evil effects of tobacco or alcohol, nervous exhaustion brought on by over-excitement, or the action of the passions. There is an individual energy or power in the heart of every man, which can alone be properly estimated when it has been tested in different ways, subjected both to physical and mental strain. In this factor consists the tonicity of the heart, a normal property of its muscular tissue, which, if it be diminished, degraded, or lost, results ultimately, and almost surely, in more or less dilation or enlargement in size and weight.

Not a *true* hypertrophy, let us bear in mind, which *invariably* should mean increased propulsive power and energy, but rather that changed and morbid cardiac condition which carries with it always the idea of incompetency or lack of healthy force.

In this connection I beg leave to refer to illustrative cases:

Case I.—J. C——, aged eighteen, single, cabin-boy on board coaster; has always enjoyed excellent health, and had uniformly good habits until three weeks ago. At that time, after a prolonged spree, in which he indulged freely in smoking and drinking, he was attacked with sudden pain in the præcordial region, accompanied with dyspnœa and palpitation. Some cough and diarrhœa during twenty-four hours. Complains now of moderate dyspnœa, which is constant. Exertion or excitement increases this symptom notably, besides bringing on cardiac palpitation. At present he sleeps well, and has no cough. He has not worked since he was taken with the symptoms referred to above, has not smoked, or committed any excess. Patient admits that he has had for many years "short wind" when he runs or exerts himself vigorously. During the past two years he has had no suffering from this cause.

Physical examination shows that the heart is normal in size; no murmurs; regular action; impulse at apex normal in force; both sounds in this region somewhat accentuated; at base, over pulmonic and aortic areas, the first and second sounds diminished in intensity, but clear; no thrill. Pulse, 88, regular, no intermissions, somewhat weak and depressible. The lungs revealed vesicular emphysema on both sides, moderate in amount.

Ordered, Tablets nitroglycerine, $\frac{1}{100}$ gr., t.i.d.

Three days later patient returned; no improvement.

Ordered, Tr. belladonna, five drops every six hours.

Patient not seen again.

Here, then, is an example of temporary cardiac weakness brought on, evidently, by immoderate smoking and drinking. There was no history of excessive work at any time, and nothing like physical strain, in the ordinary acceptation, had occurred. Previous to the initial symptoms mentioned, the patient had never suffered from symptoms which were referable to irregular heart action.

Case II.—P. B——, married, merchant, aged forty-one, came to my office on November 11, 1881, suffering from severe cardiac palpitation. He stated that he had been enjoying his usual good health, when he passed through several hours of excitement and anxiety at a fire, which occurred six weeks previously, and had destroyed much of his valuable furniture. Since that time he has had frequent and distressing cardiac palpitations, accompanied with pronounced difficulty of breathing. The dyspnœa was not an entirely new symptom with him, as he had occasionally noticed it before the time of the fire, but never had it been so pronounced and unpleasant as during the past few weeks. On questioning this patient closely I found that he had cardiac palpitation sometimes when he had not taken food during several hours. Horseback exercise, of which he was very fond, never occasioned it.

Physical examination showed slight increased dulness to the right of the præcordia. There was a soft, blowing murmur accompanying the first sound, and heard with greatest intensity over the xyphoid cartilage. Murmur was also heard over apex, but with very slight intensity. No mention was made of any epigastric pulsation. Pulse, 84, weak and depressible.

The patient himself was of large, vigorous frame, dark complexion, had passed several years in Cuba, and had had one or more attacks of biliary colic.

Tr. belladonna, tr. nux vomica, and sp. ætheris comp. were prescribed in moderate doses, three times daily.

In this case mental anxiety and excitement were evidently the determining factors in causing cardiac incompetency.

I might cite examples in this place from my private records to show the effect of lithæmia, pronounced gout, atonic dyspepsia, anæmia, excesses of tea or coffee, uterine disturbance, etc. in producing morbid cardiac conditions. In view of the time allotted to me I shall refrain. I desire, however, to read excerpts from notes of one case of notable cardiac displacement in connection with fibroid phthisis and old pleuritic and pericardial adhesions, in which there were no rational symptoms of heart disease. A. S——, aged twenty-four, iron-worker. Patient began to suffer five years ago from cough, dyspnœa, and moderate expectoration. Soon he lost flesh and strength, and had several pulmonary hemorrhages. At present patient has pain in his chest, and is pale and anæmic. His appetite is good.

Physical examination revealed the usual signs of fibroid phthisis and pleuritic adhesions, especially marked on the left side of the chest. Heart: The greatest intensity of the impulse was discovered one inch to the left of the left nipple. No murmurs. First sound at apex accentuated; second sound not as loud as normal. At base, over aortic area, slight blowing murmur accompanying first sound; second sound diminished in intensity. Near left nipple a friction sensation is distinctly felt. A blowing murmur is heard in vessels of the neck, which is thought to be due to changes at the aortic orifice.

Patient improved under following treatment: Creasote, ♏j.; glycerine, ℥ j.; whiskey, ℥ ij. t.i.d.; and hydrarg. bichlor., gr. $\frac{1}{16}$, with tr. cinchona comp., ℥ j., after meals, t.i.d. Local applications of ungt. iodinii were made to the chest-walls.

This case had a considerable interest for me from the fact that although the heart was drawn far away from its normal position, and the concomitant conditions were such as to interfere greatly with the circulation, yet the patient never in reality complained of the ordinary rational symptoms of cardiac weakness.

In the majority of cases of heart disease due to over-exertion, which I have encountered, the affection has come on gradually. There has been in these cases no sudden irruption of morbid changes. Symptoms have shown themselves at first, and with some differences as to their manifestations, and subsequently more or less *visible alterations*, as indicated by physical exploration, have become evident in the heart and blood vessels.

All trades of a laborious kind, and most trades should

thus be described, may be efficient causes of chronic heart disorder. Yet some occupations especially predispose to cardiac incompetency, whether it be merely functional or organic. Notably are to be found in this class those vocations in which there is continuous work with the arms, or those in which heavy burdens are frequently lifted, and where, therefore, great occasional efforts act powerfully also in producing disease. In many of these cases vesicular emphysema, more or less localized, or generalized, is such an ordinary accompaniment that I consider it somewhat remarkable when I do not find marked evidences of its presence. Other lesions —as those of the liver, spleen, stomach, kidneys (usually of the nature of congestions) (Delafield)—are frequently secondary to the cardiac disorder, and modify it as complications rather than as causes. In order to be explicit and guarded in the interpretation of the cardiac cases I am studying, I would say here that I eliminate such as are found in individuals who have suffered previously from one or more attacks of well-marked articular rheumatism. I do this because rheumatism of the joints is such a frequent cause of *valvular* disease that its pre-existence might invalidate some of my observations. In regard to the use or abuse of alcohol my stand-point is somewhat different. Alcohol, when it affects the heart injuriously, shows its evil results ordinarily in the muscular fibres or the vascular walls, and not directly at the heart orifices. Fatty degeneration of the former, with more or less atheroma of the latter, are familiar changes which bear witness after death to its poisonous effects. When, therefore, such changes exist during life, the development of symptoms of cardiac weakness may be considerable and rapid in a given case from a relatively small amount of physical strain. The diagnosis, however, of these changes in their early stages is a matter of extreme difficulty, and is, I believe, made at times chiefly by reason of the manifest inefficiency of our ordinary means to strengthen cardiac systole, and by our tactile investigation of arteries within reach (temporals, radials).

Even these diagnostic tests may sometimes lead us into error, since our touch is occasionally deceptive, and our poor therapeutic results may depend upon imperfect knowledge and use of drugs, and nothing wholly satisfactory can be affirmed unless the patient dies and an autopsy is made. The first symptoms of cardiac strain or weakness are usually rational. These are—1, palpitation; 2, præcordial pain; 3, dyspnœa. All of these may be present; one, two, or all may be absent. Ordinarily the first symptom of over-exertion is cardiac palpitation. This symptom at first appears after prolonged effort, or some instance of *temporary* and *unusual* exertion. As an example of this kind the following case is interesting:

Case III. *Cardiac irritability or heart-strain; slight cardiac dilatation, with incompetency of the mitral valve; areas of pulmonary emphysema; subacute gastritis.*—W. H. R——, aged forty-five, driver, came to New York Hospital, Outdoor Department, October 15, 1886. Patient has suffered from palpitations of the heart during the past twenty years. They began when he served in the United States Army in 1862. One month ago he was attacked with acute diarrhœa and profuse bloody stools. Since his convalescence, a period of three weeks, he suffers from a sensation of weight over the stomach, particularly after meals. He has moderate pain now at all times over the epigastric region, and this pain is notably increased by pressure. The xyphoid cartilage is very tender when it supports any weight. These pains came on suddenly after lifting a heavy case, and about one hour subsequently.

Physical examination to-day (October 15, 1886) shows marked epigastric pulsation. Apex-beat of the heart is not visible, nor can it be accurately located by palpation. The area of superficial cardiac dulness extends from the xyphoid cartilage slightly to the left of a vertical line passing through the left nipple. The first sound of the heart is accompanied by a moderate, soft, systolic, blowing murmur.

℞. Tinct. strophanthus .... ℥ ss.
Syrupi aurantii..... ℥ ij.
M. Sig.— ℥ j. t.i.d. after meals.

October 18th.—Feels better; has not sensation of pressure over the heart; pain in the epigastric region about the same. Pulse, 100; regular, no intermissions, depressible. Slight blowing murmur at apex; apex-beat still very difficult to locate, except by auscultation. Patient states that every time he has lifted a heavy burden during the past ten years he has suffered from pain in the region of the heart and over the left hip and from *palpitations.*

He has never suffered from dyspnœa after making excessive physical efforts until two weeks ago. Since that time, when he remembers having lifted a heavy bar of iron, he has had considerable difficulty of breathing, even after moderate exertion. During the same period, also, he has suffered from the sensation of a heavy weight over the stomach. He never had this symptom before the time mentioned. Patient's legs are not swollen; he passes about his usual quantity of urine. On examination there is no albumen present. Patient never drank to excess. His use of tobacco is moderate. No history of syphilis.

℞. Repeat strophanthus.
Pulv. lactopeptin, gr. x., after meals.

October 25th.—Complains of palpitation, occasional pain in the præcordial region, less dyspnœa, pain in epigastric region, eased by pressure and increased by walking.

℞. Fl. extr. convallaria.
Sig.—Gtt. x. every four hours.

1. Sometimes palpitation shows itself when the patient is seated, and resting after a meal, or when relatively weak from lack of food during several hours. Occasionally patients are awakened from sleep at night with most distressing subjective feelings of cardiac palpitation. As an instance of this kind I offer the following:

Case IV. *Weak heart occurring without discovcrable cause; palpitations; dull localized pain over præcordia; vague feeling of oppression; no evident dilatation or hypertrophy of the heart.*—Mrs. F——, married, aged forty-two, gives a doubtful malarial history; came to my office on March 26, 1885. At that time she complained of the following symptoms: A raw sensation in the throat, no cough, expectorates occasionally a small quantity of white viscid phlegm, suffers a great deal from a weak and a dull sore feeling at the epigastrium. These abnormal sensations are relieved for a while by a moderate amount of light food, and particularly by stimulants. Patient has no flatulence and no other dyspeptic symptoms; bowels are regular. Patient is a great sufferer also from cardiac palpitations, which come on with no assignable cause. Her heart flutters and quivers, especially at night, when she first goes to bed, and this symptom is about equally severe in any decubitus. After sleeping a few hours, when she awakens, her heart beats tumultuously and painfully. On physical examination the heart is of normal size, beats feebly, but no murmurs are discovered. Veins of left arm are quite prominent. Patient complains of defective circulation—always feels tired. The weary, gone feeling is located especially over the præcordial region. If patient did not take a long, deep inspiration occasionally, she feels as if her breathing would stop altogether. Treated by stomachics, quinine and arsenic, heart tonics, during five weeks with no beneficial effects.

To some of these patients the heart appears to beat very rapidly, tumultuously, and with increased force. To others the heart flutters, quivers, beats irregularly, with diminished energy, and occasional intermissions are noted in the radial pulse. These different sensations

are observed by the patient and reported to the physician. I have known, on several occasions, such palpitations to be the cause of much mental distress, and particularly is this statement true of those palpitations which take place during the night and occasion great fright when the patient is awakened by them.

2. It is no unusual thing to have these palpitations accompanied by notable dyspnœa. This dyspnœa may also show itself previous to, or subsequent to, the palpitations. When it exists at the time the patient is suffering from palpitations it is very distressing. The patient feels, on rare occasions, as if he would actually stifle; and if in the recumbent position, is obliged to raise himself to a sitting posture to obtain the air essential to the demands of respiration. Ordinarily the dyspnœa is much less, or milder in type, and is merely sufficient to aggravate and heighten the suffering occasioned by the palpitations. This is true when the patient is quiet. When any physical exertion is made the dyspnœa is *increased*, as a rule, and yet, singular to say, I have seen those in whom moderate exercise in walking, or riding on horseback, did not increase dyspnœa. Dyspnœa may be the first symptom accused by the patient. He may have no cardiac palpitation; he may not feel his heart at all. He is simply conscious at times of the desire to inflate his lungs thoroughly, and thus inspire all the air possible. He has a somewhat oppressed, weighty feeling in the chest anteriorly, which is almost always present. He recognizes easily this abnormal sensation, although he cannot always define or describe it. This form of dyspnœa may not be increased by the advent of cardiac palpitations, although it usually is. As an example of this kind, I offer the following history:

Case V. *Cardiac weakness following moderate dilatation and hypertrophy, probably caused by rowing; congestion of the liver, accompanied with slight jaundice, perversion of taste, and dizziness.*—W. L——, married, aged thirty-two, merchant, came to see me professionally June 4, 1886. He complained of difficult breathing, the cause of which he was unable to assign. His bowels were regular, and there were no symptoms of dyspepsia. During many years he was very fond of athletic sports, especially of rowing, to which he had devoted himself. He has always been temperate in his habits, smokes moderately, and only drinks tea or coffee once a day. At present his skin is somewhat muddy, and his sclerotics have a yellowish tinge.

Physical examination shows somewhat dilated and hypertrophied heart. Its action is regular and tolerably strong. There are no murmurs. Moderate bulging of both sides of the chest anteriorly indicates the presence of pulmonary emphysema, which assumption is confirmed by percussion and auscultation. No bronchitis. Spleen normal in size. Liver *somewhat* enlarged, the enlargement being probably due to congestion. Two or three weeks ago, on presenting himself for examination at a life-insurance company, he was refused, on the ground that he had an "athletic heart." His urine was carefully examined, and proved to be normal. I prescribed (June 15th) carbonate of ammonia, belladonna, and ignatia, several times a day, and told him to continue the treatment several weeks.

November 11, 1886, five months after I first saw my patient, he wrote me that he had never felt better, and weighed twenty pounds more than when I last prescribed for him. "This may be," he writes, "because I took little or no exercise last summer. Following your advice I did not row at all, and previously I had been in the habit of rowing a *great deal* during at least twelve years back. I took about three bottles of the medicine you prescribed, and think this must have done the business, as after that I did not have any trouble, either from palpitations or from shortness of breath. My appetite has been splendid, I sleep like a top, and, in fact, my health has been generally fine. As regards my life insurance, I was passed by the New York Life Insurance Company, and, after passing through the hands of about ten doctors, was pronounced a good risk."

3. Pain in the præcordial region is a symptom of considerable value at times, as pointing to cardiac weakness, but cannot be relied upon as confidently as dyspnœa and palpitation in making this diagnosis. It may be present here, and be nothing more than the evidence of localized neuralgia in the pectoral or intercostal muscles. Frequently, pain in the epigastrium is undoubtedly due to heart-strain or heart-weakness; again, it is but the symptom of subacute gastritis quite independent of cardiac debility. These facts have been latterly insisted upon by Dr. P. Müller. In his recent thesis on the subject of cardiac dyspepsia, he "maintains that there are few affections of the heart which are not accompanied, at one time or another, by gastralgia, dyspeptic troubles, or even serious lesions of the stomach."[1]

Pain in the left axillary region may be attributed to the heart, when it is caused entirely by localized pleuritis. There is a dull, heavy, constant pain seated over the right ventricle, which is usually increased by slight pressure (although not always), and which I have learned to believe is of cardiac origin.

The following case is an exceptional one, in which *pressure* relieved this pain temporarily:

Case VI. *Aortic regurgitation; hypertrophy, with dilatation of ventricles; syphilis; no rheumatism; overexertion; principal symptom, localized pain.*[2]—M. D——, married, aged twenty-eight, laborer, English, came under my care November 17, 1874. Patient has been suffering two and a half years. Previously never ill. Had syphilis ten years ago, followed by secondary symptoms; been a free drinker. His symptoms began with pain in back. Six months later had pain in præcordial region. This pain persists at present; is most intense at night, and often prevents sleep. It is brought on during the day by any physical effort. It can usually be relieved, for a time, by pressure over the heart. Patient often vomits during attack of pain. Has been slightly jaundiced several times; does *not* suffer from *dyspnœa* or palpitation. Pulse, 84; respiration, 20.

Physical examination shows aortic regurgitation, hypertrophy, and dilatation of heart.

Ordered iron, potass. iodid., empl. bellad., light diet.

Sometimes sharp, lancinating pains in the præcordial region, which show themselves suddenly and then disappear as quickly—pains which shoot up the neck and down the left arm, pains which have none of the intense and indefinable agony connected with them that mark those of true angina, and which do not leave behind points upon which pressure with the fingers brings out a cry—these pains, I believe, are frequently of cardiac origin. Not that I believe they are *seated* in the heart,[3] but at least they show themselves often in connection with other evidences of cardiac strain, and are, moreover, present when there is no proof that they can be fairly attributed to changes in adjacent organs or structures.

Curious to say, I have met cases—not frequent ones—where the patient gave such a history, and showed such physical signs as could be explained solely by the preexistence of prolonged anterior effort, and yet, despite these facts, had never consciously suffered from the rational symptoms to which I have previously referred, and which ordinarily point, with unerring certainty, to heart-strain. In such examples we must interrogate the pulse and the heart itself. It is only at a later period that the urine, or the condition of the lower limbs, makes the presence of heart-strain additionally evident.

The pulse is usually, in the first stages of heart-strain, somewhat accelerated, and this is especially true if the strain of the heart follow any sudden or intense effort.

[1] Vide Medical Record, December 11, 1886, p. 659.

[2] In this case the cardiac hypertrophy was considerable when it came under observation.

[3] I am familiar with the old belief that the heart itself is insensible.

It is also true when the heart has been called to do more work than it can accomplish during the convalescence from acute febrile disorders, and when the fibres have not wholly recovered from physical changes which had previously affected them.

This statement, however, has its exceptions, and of these I would like to direct attention to the following:

CASE VII. *Heart-strain following chagres fever and pneumonia.*—T. M——, single, student, twenty-three years of age, came under my care October 11, 1886. At that time he complained of frequently recurring nausea, and of an ill-defined feeling of malaise over the chest anteriorly. Patient contracted Chagres fever on a trip to Panama three years ago, and since that time has often had symptoms of gastric irritability and torpid liver.

Ordered Pil. extract. colocynth., quinine, and belladonna, t. i. d.

November 6th.—So far as stomach is concerned, feels well. Still complains of occasional headache, although it is less frequent and painful than it was some weeks since. Upon running a short distance he suffers from great oppression and his heart seems almost to stop. These symptoms come on at times immediately after slight unusual exertion; at times several hours elapse before they manifest themselves. Whenever they occur, they invariably last several hours. Sometimes the oppression and apparent cessation of heart-beats occur without assignable cause. Occasionally the attack will occur during the night and awaken him from sound sleep. During its duration, which often lasts, off and on, several hours, he feels as if he would die. He had pneumonia of the right lung three months ago, and since his recovery from that disease has been considerably worse than ever before. Stimulants usually relieve him somewhat, even when he is suffering most acutely.

Physical examination shows pulse 72 per minute, quite full and strong, although somewhat irregular: no intermissions. Heart: Apex-beat carried somewhat toward the left of normal beat, in sitting posture. No marked increase of area of dulness over præcordial area; no thrill; no marked irregularity of cardiac beats appreciable upon palpation; soft blowing murmur at apex, preceding first sound of heart and following second sound. At base of heart, especially over aortic area, slight blowing murmur accompanies the first sound. This murmur is also heard in the vessels of the neck. The second sound of the heart at the base is *clear* and *normal* in strength.

Ordered Tablets tr. strophanthus hispidus, āā ℥ij., t. i. d.

November 9th.—Patient has taken medicine regularly; feeling in better condition, and not so much troubled with oppression as he was; has had no palpitations (although has not run at all for some days); has not had such an intense desire to take a long breath from time to time, which previously was imperative and recurred constantly every few moments. Patient can wear his vest buttoned; before he began strophanthus he was obliged to open it to give himself some relief during his attacks of oppression. He is not nervous, and his symptoms do not appear to be due to flatulent dyspepsia. Respiration, 24, regular, somewhat shallow; pulse, 76, somewhat more regular. Heart-systole decidedly more forcible; blowing murmur at apex and base more marked than last time; no epigastric pulsation visible; urine increased in quantity. Repeat strophanthus, and in addition take pill of iron, arsenic, and quinine, t. i. d., at meal-time. All very active exercise prohibited for some months. A day or two later, patient left the city and went to Virginia.

November 28th, I received a letter from him in which he still complained of feeble heart-action and persistent headache; his appetite was good and bowels regular. Despite, however, these facts, and although he lives a great deal in the open air, he has continuous cold extremities, and is unable to keep them warm.

In instances, on the other hand, where the sum of physical effort each day is very considerable, as in the vocations of numerous workers (typesetters, shoemakers, plasterers, painters, weavers, etc.), although upon no single occasion is there any excessive physical effort, the pulse is ordinarily somewhat slower than normal.

The pulse which beats rapidly *may*, or *may not*, be weak and compressible. These qualities of weakness and compressibility are, however, adjoined most frequently to the slow pulse of prolonged heart-strain. Irregularity of the radial pulse-beats is often observed in both classes of cases. Evident intermissions in the pulse are not observed in the primary stages of heart-strain. In fact, it is only when the heart-fibre is evidently somewhat degenerated, or the cavities have become manifestly enlarged, that I have been able to notice occasional intermissions. When sphygmographic tracings have been taken, especially in advanced cases, they have shown marked lowering of arterial tension.[1]

The heart itself is in a variable condition. At first, and even subsequent to repeated and great physical efforts of *somewhat temporary* nature, the heart shows no evident increase of size. Its sounds may or may not be notably weakened. Sometimes both sounds of the heart are clear and markedly accentuated, and have almost a metallic clang or tone. This metallic ring I have heard far oftener accompany the first than the second sound. As I have remarked in the radial pulse, so I have noticed in the heart, that the beats are more rapid, as a rule, when there has been acute cardiac strain; when the strain is the result of almost continuous physical effort, during many years of severe labor, the heart-beats are ordinarily somewhat diminished in frequency as compared with those of perfect health. In either case there may be some irregularity in the force and rhythm of successive beats. True intermissions in heart-systole are only recognized when close observation already indicates advanced organic changes, causing degeneration of muscular fibres, or their distinct stretching or dilatation. A soft blowing murmur, heard more or less distinctly over a large portion of the præcordia, is not infrequent. It is usually heard with most intensity near the apex. It may be loudest over the aortic area, or at the xyphoid cartilage, and indicate aortic regurgitation. Inasmuch as the former murmur sometimes disappears after weeks or months of treatment, I have under these circumstances considered it to be due to temporary dilatation of the mitral orifice, brought on by relaxation of the cardiac walls.

Except for its presence, it would be often difficult to say positively that the heart gave evidence of any organic change. This murmur, when it accompanies the first sound of the heart, may possibly be allied with the blood-condition of general anæmia. Whenever the murmur is not heard synchronous with the first sound of the heart, either at the base of the heart or in the vessels of the neck, it cannot properly be confounded with a blood-murmur. Frequently the sounds of the heart are somewhat reduplicated. This reduplication of itself *shows weakness of the heart*, and possibly that the walls of the *two* ventricles do not contract synchronously[2] with each other. No thrill is ordinarily detected over the cardiac region.[3] At first, as I have stated, there is no enlargement of the heart, and this organ may be considered as affected with mere functional disorder. As time elapses, however, and particularly if the daily strain, physical or mental, continues, the heart shows evident signs of slight enlargement, due to dilatation of the cavities and *thinning* of the cardiac walls. It must not be thought that it is invariably an easy task, in physical diagnosis, to make out in a satisfactory manner the signs of enlargement of

[1] This fact was shown to the members of the Practitioners' Society at the meeting held December 3, 1886. Case of H. W——, vide MED. REC., December 18th.

[2] I have reported a case further on, in which the reduplication appeared to me to be explained by the existence of an adherent pericardium.

[3] The exceptions to this rule are found only in cases in which heart-strain has produced evident sclerotic lesions of orifices or valves.

the heart. Occasionally the accompanying conditions obscure this change very much. There are many instances in which more or less pulmonary emphysema is present, that either changes the heart's position or else covers it in a large area. If together with this concomitant state the heart is beating feebly, inspection and palpation reveal but little, if anything, that is reliable. Percussion is, also, very puzzling. We may be able thus to limit the heart accurately toward the median line, but above, below, and to the left it will often leave us in very considerable uncertainty. Auscultation will at times enable us to fix the greatest intensity of the first sound of the heart, and hence to assign the correct location to the apex; but even auscultation in instances of very weak heart will leave us in doubt, *i.e.*, in certain cases of convalescence from fever or other acute disease. Of course it should be understood that I am referring ordinarily to cases of slight enlargement of the heart, since in almost all cases in which the dilatation, with or without slight thickening of the ventricular walls, is at all pronounced it can be unerringly stated. In cases of heart-strain, or weak heart, which occur in the *higher classes*, it is a most unusual circumstance to find, concomitantly, evidences of arterial degeneration, at least among youthful subjects, occasioned by a similar morbid process to that which produced the cardiac disorder. Among the toilers, or those whose whole existence is one persistent manual effort, it is very frequent to note accompanying arterial changes which indicate commencing or advanced sclerosis. I have encountered already more than one case of sudden regurgitant murmur, heard with the second sound of the heart, and propagated downward and to the left, which I felt confident was due to sudden rupture of one aortic cusp. I have never met with any murmur which I thought should be explained by rupture of the mitral or tricuspid valve,[1] but relative incompetence of these valves, as shown by rapidly developed murmurs, which continued during many months without change and despite appropriate treatment, have convinced me of the possibility of *acute dilatation* of the *mitral* and *tricuspid* orifices, which was more or less lasting, and at times, although by no means always, of serious import.

The following is an instance of the former kind, which I consider important and suggestive:

Case VIII. *Acute heart strain due to over-exertion in attending to household duties, etc.*—A married lady, forty-one years of age, mother of several children, had quite obstinate bronchitis during several winters. Also had, after birth of last child, during a year or two, somewhat excessive menstrual flow at each monthly period. Other than these affections, patient has always been an extremely vigorous woman. During the late Christmas season patient tired herself a great deal with shopping, visiting, making arrangements for home entertainments, etc. She sat up late and rose early in the morning. She was on her feet almost constantly during fifteen to eighteen hours of the twenty-four, and had upon an average, during a period of one week, only about six hours' sleep each night. Two days after Christmas my patient was taken suddenly with pain in the epigastric and præcordial region, and fluttering or palpitation of the heart. The sensations in or around the heart were quite distressing and made her feel anxious. Patient also had a choking sensation in the throat, syncopal tendency, especially when she had been without food several hours, and intense headache. There were no signs of dyspepsia; bowels regular; no signs of pleurisy or intercostal neuralgia. Upon auscultation there was a soft blowing murmur synchronous with the first sound, and heard with most intensity below and inside the left nipple.

The second sound at the same level was also somewhat impure, but this impurity was scarcely sufficient to be characterized by the term "murmur." The pulse was somewhat frequent, quite weak and depressible, and showed slight irregularity of successive beats. In the course of one week relative repose, more prolonged sleep at night, and the use of wine of coca several times a day, together with two or three milk-punches in twenty-four hours, restored the patient, apparently, to her former condition of vigorous health. The blowing murmur at the heart-apex had diminished, but not entirely disappeared. In the case just reported I recognize distinctly a case of acute heart-strain, moderate in degree, and of short duration. Cases similar or analogous to this one I have frequently seen. No doubt every general practitioner is familiar with them. At the same time I feel obliged to add that they are frequently ignored, and I do not believe that they have yet been emphasized sufficiently by writers on medicine so as to make the condition one which is to be constantly looked for, and, when encountered, to be energetically and judiciously treated. There are thousands of men and women in our large cities—brokers, bankers, business men engaged in large, important, and anxious business relations; there are mothers of families, spinsters young and middle-aged, devotees of fashion, frequenters of innumerable dinners and parties—who complain at times of being tired out, run down, having need of change, of rest, of freedom from care or dissipation, and who come to their family physician for advice. Usually such patients are treated as being anæmic, or neurasthenic. So they frequently are; but, after all, what is their most imperative requirement, and which is the *organ* most at fault and most needing rest? Many, many times I could answer truthfully, it is complete repose of body and mind that they require, and *the heart* is the *organ* which gives signs of special weakness—functional or organic, or both.

We should, therefore, in my opinion, recognize in all prolonged, continuous, and undue physical or even mental effort the source or origin of many morbid cardiac conditions.

As an example of the latter I offer the following:

Case IX. *Weak heart; cerebral and spinal anæmia, caused by mental overwork.*—Mr. B——, aged thirty-five, private tutor, married, smokes and drinks moderately, formerly much given to athletic sports, came to see me November 1, 1884. During past few years this patient has become mentally exhausted through continuous teaching and study. At present he complains of painful points over lower cervical and upper dorsal spine. This morning had an attack of "goneness" at region of heart; relieved by whiskey. During the past summer, and at the present time, patient has frequent fluttering, and very weak, distressing ("gone") sensations in the præcordial region.

Physical examination shows weak, slow cardiac action, and markedly weak pulse; no other evidence of structural lesion of the heart.

Ordered Tr. digitalis, ammonii carb., and ergot, in moderate doses, every four hours. Thermo-cautery applied to back of neck; mild galvanism to cord and brain daily.

November 22d.—Heart continues to annoy him a great deal, especially at night.

December 1st.—Complains of heart principally—feels weak from heart—otherwise would be strong and well. Yesterday had a pleasant evening at home; went to bed feeling bright and well. In a short time after going to sleep, awoke with a sinking sensation around the heart, accompanied by nausea, and numbness of the lower limbs. These horrid sensations lasted four hours, despite ergot-mixture, ammonia, local friction, etc. Condition of heart last spring was one of over-excitation; so much, indeed, was this felt to be true that my patient thought at times his heart would rupture from excessive action. At present there is extreme weakness of heart action, which is accompanied by a weary sensation in the back of neck.

Physical examination to-day reveals a soft, blowing murmur, not loud, heard at the apex of the heart, and in the vessels of the neck, and accompanying the cardiac

[1] Such cases have been reported by Da Costa. See III. Toner Lecture, Washington, 1874.

systole. The countenance is pale and there is evident anæmia. No history of malaria.

Ordered Pil. Vallet, t.i.d. Smoking, tea, and coffee forbidden.

December 30th.—Suffered a great deal from weak feeling around the heart three days of the present week. This unpleasant sensation is more relieved by the use of convallaria than by that of digitalis. Patient is stronger, less irritable, sleeps better, and his heart troubles him less frequently and less intensely than it did two months ago.

While a cardiac dilatation may become developed in the manner referred to, I cannot doubt that not infrequently, after great or frequently repeated physical effort, myocarditis and fatty degeneration of heart-walls will surely be effected. Occasionally we may indeed look for a sudden rupture of valve, giving rise to all the secondary effects of such a condition, or for an inflammation of orifices, which will sooner or later become allied with chronic sclerotic changes at these regions and throughout the arterial system. One of the surest indications of heart-strain, or weak heart, when it is found, lies in the alterations of the urinary secretion. The bulk of the urine may not vary notably at first. Soon, however, it lessens or increases in quantity, and deepens in color, or becomes more watery. The former condition is that indicative of lowered heart-power, especially in so far as it affects the cardiac muscle. The latter state shows marked nervous irritability, and is apt to occur whenever the heart-strain is the result of excesses in which mental impressions are most active. I have remarked it whenever the cardiac strain was under the evident influence of intense study, late hours, undue excitement of business, pleasure, or sexual relations; of abuses in the use of tobacco, tea, coffee, and alcohol. A trace, and even a moderate amount, of albumen has been noted in the urine more than once, when neither the number nor nature of the casts, the rational symptoms, or, indeed, the general condition pointed very clearly to the existence of chronic renal disorder. The following case appears to me of some interest in this connection:

Case X.—H. W. J. T——, single, aged thirty-five, came to me last spring, stating that he had been refused by life insurance companies on account of presence of notable quantity of albumen in his urine. At that time he had few or no rational symptoms of disease of the kidneys. On examination, specific gravity of urine was 1.026; distinctly acid; no sugar; no bile; urea, sixteen grains to one ounce; micturition regular; albumen, fifteen per cent.

Patient was advised to drink abundantly of milk; to rest from business cares as far as possible, and to take tr. ferri perchlor. in moderate doses. At the end of June patient passed under the care of Dr. A. L. Carroll, of Staten Island.

On July 31, 1886, Dr. Carroll wrote me that the examination of urine on June 22d showed eighteen per cent. albumen; on June 30th, twelve per cent.; on July 9th, twenty-three per cent.; on July 27th, twenty per cent. Specific gravity from 1.022 to 1.028.[1]

In specimen of July 9th two or three small hyaline casts were found; in the others, *none*. Sphygmograph showed rather high tension. Dr. Carroll thought he detected some indications of "strain" of the right heart, and wrote: "You are, I presume, aware that he (patient) was for a long while enthusiastically addicted to athletics, especially to rowing contests, and that his mother has valvular disease. The absence of other symptoms in his case, and the persistently large quantity of albumen, seemed to me to negative a purely local causation of increased blood-pressure, particularly when considered in conjunction with the maintenance of the excretory renal functions." Patient "professes to feel quite well physically." "Whether to ascribe his disorder to obscure right-heart obstruction, to incipient waxy kidney, or to some persistent local lesion," was an undetermined matter to Dr. Carroll as to myself, at the date of the letter referred to above.

Between July 31 and September 26, 1886, Dr. Carroll saw our patient twice. "On both occasions the albuminuria was increasingly persistent, and the last specimen of urine examined contained a very few small hyaline casts, though no other anatomical elements. The specific gravity was 1.031; albumen, twenty-eight per cent. (by volume) (August 23d). Total amount of urine daily about normal (?). "The patient expressed himself as feeling perfectly well in all respects." Dr. Carroll and I at this time believed in the existence of chronic parenchymatous nephritis, although I agreed with him "that it was something new to find so few casts in this condition after an undoubted existence of more than five months, and probably much longer."

October 4, 1886.—Examination of urine showed—"specific gravity, 1.024; albumen, twenty per cent.; two or three narrow and extremely transparent hyaline cylinders, . . . mere albuminous films, requiring delicate management of illumination for their detection." "In many hundreds of urinalyzes," says Dr. Carroll, "I have never met with a case which puzzles me to such an extent." A few days later Mr. T——, at my suggestion, was put on tincture of strophanthus, with the approval of Dr. Carroll.

On October 1, 1886, I made the following notes at my office when Mr. T—— called to see me: "Looks pale, although he says that he feels very well. No œdema of face or limbs; has had headache only once during the past few weeks; appetite fair; heart does not annoy him; has had once or twice cardiac palpitations on awakening suddenly at night; no dyspnœa; no præcordial pain. On physical examination I find heart-sounds rather weak; apex-beat somewhat difficult to localize by palpation; am able to do so by auscultation, and find it beats below left nipple in sixth interspace; no murmurs; regular pulse, 72; no pain in back." [Thought abuminuria might perhaps be due to deficient heart action.]

On November 8th Dr. Carroll wrote to me that he had seen Mr. T—— twice since he began taking strophanthus, and continued his letter as follows: "On the first occasion there was little or no indication of its action in the sphygmographic tracing, and I increased the dose. At his second visit there was a diminution in the amount of albumen. On October 18th the specific gravity of the urine was 1.024; albumen, one-fifth; on the 30th, specific gravity, 1.023; albumen, one-seventh. In neither instance did I find casts. He says that he feels remarkably well."

On November 30, 1886, Dr. Carroll again wrote to me in regard to Mr. T—— (in answer to my request by postal to know how he was) as follows: "Mr. T—— has been unable to renew his supply of strophanthus for more than a week before his last visit to me (on November 21st); but the effect of the drug seemed to be continued. The amount of albumen was at that time further reduced to one-ninth by volume; specific gravity of urine, 1.026."

Remarks.—In view of the interest of this case, as it seems to me, I have requested Dr. Carroll, and received permission from him, to use the observations contained in his letters to me. I have not hitherto been able to decide to what degree precisely the condition of the heart has been instrumental in occasioning the albuminuria. That it does cause a part of it seems fairly probable. And, if this be true, I think we shall be prone to admit that, in certain instances, a heart which is undoubtedly somewhat dilated, and even though the usual rational symptoms of its incompetency are lacking—*i.e.*, dyspnœa, pain, palpitations—yet the amount of albumen eliminated by the urine may point indubitably to the fact. If our case had been accompanied by diminished amount of urinary excretion it would be, in my opinion, less conclusive than it is, in view of what we know of Bright's disease. Of course one such case

[1] The albumen was estimated by volume.—A. L. C.

as the foregoing does not prove my proposition; but, as I believe I have seen analogous conditions several times previously, I now wish to call attention to them.

The following case is of interest in showing, among other matters, the fact that when there is notable cardiac weakness in connection with co-existing or pre-existing chronic renal disease, the use of cardiac tonics may increase manifestly the quantity of albumen eliminated by the kidneys, while the bulk of urine is not much increased even during the early days following its administration, and later diminishes considerably. This case is likewise of value as affording evidence of the fact that pulsation in the second, third, and fourth left intercostal spaces is not invariably found in cases of cardiac dilatation and weakness, contrary to the view ably supported by W. Russell.[1]

CASE XI.—J. C. H—— entered St. Luke's Hospital March 23, 1886. Patient had pleurisy in 1883, and since that time suffered occasional pains in præcordial region. Syphilis in 1882. Occasionally drank to excess. Formerly very athletic. Latterly urine increased in quantity; specific gravity, 1.012; acid; albumen, five per cent.; hyaline casts; round epithelium; leucocytes.

Examination of heart.—Apex fifth space, just inside mamillary line; reduplication of second sound over apex, with roughening preceding first sound. Heart rapid, regular, and feeble; difficult to determine positively nature of murmurs; weakness of heart action especially notable over right ventricle; sounds of heart heard with greatest distinctness over lower portion of sternum and at epigastric region. There is a very limited area of pulsation just inside of left nipple; none at epigastrium, and none over left intercostal spaces. Some pulsation visible at root of neck on both sides, and over sternum, when patient lies in dorsal decubitus; pulse, 96; regular.

December 5th.—℞. Caffein citrat., grs. v., t.i.d.

December 14th.—Albumen in urine, twenty per cent.; passed thirty ounces.

December 19th.—Albumen in urine, thirty-seven per cent.; passed thirty-six ounces.

December 27th.—Albumen in urine, six per cent.; passed twenty-eight ounces.

January 3d.—Albumen in urine, twenty per cent.; passed twenty-six ounces.

January 8th.—Patient died of acute pulmonary œdema.

Autopsy revealed both layers of pericardium adherent; mitral orifice somewhat contracted; cardiac cavities dilated; left ventricular wall thickened. Kidneys showed changes of chronic diffuse nephritis.

In marked heart-strain, and especially when there is a reasonable probability of the production of slight or moderate cardiac dilatation, the lower limbs are often œdematous. This œdema is always more marked toward the end of the day; in the morning it has almost as completely disappeared. In those cases in which the pulse is extremely rapid, feeble, and somewhat irregular, the heart also is very rapid and weak, palpitations excessive, and stomachal distress quite pronounced, and the cardiac strain appears to have affected directly the cardiac motor ganglia, or the sympathetic system more than the cardiac muscular fibre. While this statement is in part correct, there may also be present in such cases sufficient evidences of some enlargement of the heart, mainly due to dilatation of its cavities. This cardiac dilatation may be secondary to a condition of slight anterior hypertrophy, and may be produced by kidney disease, endarteritis, or as the result of valvular disease, "and it is impossible," according to Janeway, "to determine how far dilatation of the cavity, or degeneration of the muscular tissue, is predominant in the production of the ensuing phenomena."[2] I would say, in regard to this opinion, while often true, that at times our therapeutic means will enable us to clear up the situation, since in the case of pure dilatation decided amelioration will result from continuous judicious treatment, whereas this can scarcely be looked for if degeneration of the heart-muscle be present.

The case of W——, who was presented by me at a late meeting of this Society, admirably illustrates, in my belief, some of the preceding statements.[1]

In those cases in which the pulse-rate is remarkably slow, the pneumogastric trunks probably lack their proper supply of oxygenated blood, owing to heart weakness. In some of the most remarkable of those examples reported by Flint,[2] they were thought by him to bear evidence of morbid central disturbance associated therewith. Numerous cases in which idiopathic dilatation of the heart[3] had advanced to the degree of producing swollen legs, a rapid, feeble, irregular pulse, and all the physical signs of dilatation, have been so much ameliorated under treatment that all these symptoms passed away. In one case, reported by Fothergill, after four months' treatment with iron and digitalis, there was such complete cure that ten years later the patient had no feeling at all of weakness about the heart.

This stretching of the muscular tissue, with enlargement of the cardiac cavities, often follows conditions of passing debility, and may, under such circumstances, be recovered from completely.[4] It is wise, however, to note that the general condition may often be dependent on the feeble heart, rather than the reverse, which is, also, none the less true that the feeble heart is but a direct consequence of the adynamic state of the patient. A feature in the chronic affections of all our internal organs, which has long appeared to me one of extreme interest, is what may be termed the inherent vitality, or strength of each one, in different individuals. This strength can alone be properly estimated when it is submitted to certain tests. And while one person may bear these tests so well that apparently no evil results follow, another person, with an outward aspect of far greater vigor, will fail soon and utterly. This is one of those important facts that most trainers and all educated teachers of physical exercises for the healthy development of the body are becoming daily more familiar with. Owing to this knowledge we are less likely in the future to see among our young men, brought up in schools and colleges, the diseases which undoubtedly result from excesses of rowing, tennis, bicycling, running, and all outdoor sports or contests in which vigor of body and strength of limb are essential.[5] Some of these diseases, it must be recognized, give evidence of their presence by such signs as accurate physical diagnosis can generally discover and properly estimate. Alongside of such cases, however, there are a large number of others, I am convinced, in which no outward signs betray the tiring or exhaustion of the cardiac muscular fibre. It has been stated by some observers that when the heart-fibres are in a perfectly healthy condition they cannot be thus strained, either by physical or mental over-exertion.[6] Spillman maintains that "the heart wearies not. It is formed to beat. That is its rôle, its life. It beats sixty, seventy, and eighty years without wearying." According to such views the word "over-exertion" applied to the heart is not physiological.[7]

Such statements, in my judgment, cannot be supported by the close observation of cases which are daily seen in our hospital clinics. Certain rational symptoms, when duly weighed after the history of the patient is fully taken, and all pernicious modifying influences from diseases of adjacent organs have been fairly eliminated, are

as surely diagnostic of heart-strain as the same symptoms are when accompanied by evident physical changes, or the physical alterations are without the rational symptoms. In this connection I would cite the following forcible and truthful statement from Delafield:[1] "In some of the cases the rhythm alone is disturbed; the patients have an irritable heart without any marked change in size. In other cases, in addition to the irritability, there are also dilatation and hypertrophy of one or both ventricles. . . . In still other cases, although the heart is enlarged, there is no change of rhythm, and it does not trouble the patient." After all, the heart is a working organ of which it may be truly said that the principal, all-important function is its ceaseless, intermittent activity. Now, then, are we not prone to-day to look merely, or at all events too much, at pathological results of disease which are visible to the eye, aided or not with lenses of high power? And yet these obvious pathological changes are not the *whole* disease—indeed, they are but the effects of it, and behind and beyond are the far more important etiological factors which have previously been at work, rapidly or slowly, in developing and consummating it.

If I have made myself clear in the foregoing description of those forms of heart-strain that I have personally observed many times, I have convinced you that all *physical* and *mental* over-exertion is quite capable of producing it. The amount of physical effort or mental fatigue, or both combined, essential to produce evident injurious effects must finally depend on *the individual* who may become the sufferer; and whether or not these are the *sole* efficient causes of heart-strain. Other causes may be present, which of themselves are sufficient to produce symptoms of heart-strain, and which, of course, when added to great physical and mental effort, act more speedily and disastrously. Such causes are previous existing cardiac affections of the valves and orifices, chlorosis and anæmia, fatty heart in corpulent persons, old age, pregnancy, convalescence from acute diseases of mild or grave character (Leyden). In the latter instance, particularly, we shall frequently note symptoms of heart-strain after physical or mental effort of very moderate amount. I have known, under these circumstances, attacks of fainting and vertigo to occur, accompanied by a feeling of heavy weight in the præcordial region. When the hand was applied on these occasions over the heart, scarcely could the beats be felt during some time, and subsequently, when palpitations appeared, even though unpleasant and occasionally painful, they were far less disturbing than the previous collapsed condition of the heart, which, according to the expression of such patients, seemed "dead like a stone." As an example of the manner in which mental fatigue and lack of proper hours of sleep influence the heart and produce rational symptoms of great functional distress, I would here refer to the students who sit up to the wee sma' hours of the morning. I have known a case in which, under like circumstances, at a given moment the heart would begin to beat irregularly and tumultuously, and concomitantly with these palpitations would also appear a sense of weight in the epigastric region and an uncomfortable feeling of oppression. All these symptoms would last after they appeared until the patient had fallen asleep. The following morning, on awakening, they had ordinarily disappeared.

Finally, there are cases in which no *sufficient* cause can be assigned, after the most careful examination and inquiries, to account for the apparent cardiac debility. In such instances, in the words of Dr. E. G. Janeway,[2] "it has seemed to the writer a necessity at times to make the diagnosis of weak heart, it being impossible to determine the essential cause of such weakness. This relates to those cases in which the symptoms of cardiac disease exist, but the heart is normal, or nearly so, in size; the sounds, unless carefully noted, seem normal, no murmur is present, and there is an absence in the history and age of the true, or satisfactory, explanation for this state. I am perfectly willing to admit that after acute disease we should expect myocarditis, with pyæmia, perhaps suppurative myocarditis; with rigid radials, etc., coronary endarteritis; in a person, particularly a female, who had been a hard drinker and had fatty liver, fatty degeneration; in marked anæmias, fatty degeneration, etc." Dr. Janeway reports a case of a man, forty years of age, who after running some distance had a fainting attack. Subsequently he had symptoms which were variously attributed to phthisis and disease of the kidneys, but which Dr. Janeway explained by a weakened heart. The patient died, and the autopsy showed an old thrombus of the left ventricle, which may have formed during the syncope, and myocarditis fibrosa of the left ventricular wall. At no time during life had a murmur been audible, and, therefore, the diagnosis could be only surmised previous to death, which, however, was apparently correctly done by Dr. Janeway. Such instances are of very great interest, as showing how much "the nature of the onset and the character of the symptoms" are to be estimated in arriving at a correct diagnosis in obscure forms of *weakened heart*. In some analogous cases, still the *cause* and *nature* of the weakened heart remain completely hidden, and indeed no adequate explanation can be given in regard to their presence. In this class, according to Delafield,[1] "the physical signs of dilatation were evident." Taken absolutely, I do not believe this statement to be wholly correct, for I am confident that there are some instances in which reasonable doubt must exist as to the existence of any enlargement of the cardiac cavities. In the following remarks of Dr. Delafield,[2] however, as will be appreciated from what precedes, I agree in regard, not "to most," but to some cases of weakened heart, viz., that "no cause at all for the cardiac lesion could be discovered; and in those cases in which there was a history of sudden exertion or mental emotion, or of change in the wall of the heart, these conditions do not seem at all adequate to explain the cardiac lesion."

How are these cases of heart-strain and heart-weakness to be treated?

Manifestly the first thing to be done is to discover the primary essential cause of these affections and, if possible, to remove it. If the physical labor or occasional efforts be too great, a stop must be put to an injurious occupation. Occasionally it is necessary to abandon all work for a time and take a complete rest. Of the rapidly beneficial effects of rest there can be no doubt. At first, and when the heart-strain has been but slight and is of fresh date, it may by itself be sufficient to rehabilitate these sufferers. In many cases, however, absolute repose is not essential. Abstention from work and moderate distraction, mental and physical, are what is most required. Sometimes change of scene will afford the greatest mental relief; and as the air is also changed at the same time as the occupation and surroundings, the good effects are, so to speak, doubled. In the beginning, light diet, frequently repeated, is found more useful than to attempt to overload these patients with food. Later on the most nutritious kinds of food, in relatively small quantities at any single time, are very desirable. Aids to digestion in the form of ignatia, bismuth, ingluvin, pepsin, hydrochloric acid, lacto-phosphate of lime, etc., are of moderate value. When these fail to produce good results and symptoms of intercurrent gastritis are present, I now rely to a great degree upon counter-irritation by means of fly-blisters, several times repeated, or the thermo-cautery (Paquelin's). In two instances which I recall, I had very satisfactory results from "lavage" of the stomach. The latter method has, of course, no direct effect upon the heart in the way of invigorating or regulating it, but it certainly relieved gastralgic and dyspeptic

[1] American Journal of the Medical Sciences, January, 1886, p. 98.

[2] Loc. cit., p. 103.

symptoms in a very marked degree—and thus by reflex action, and by helping to restore normal digestive power, cardiac systole was decidedly strengthened. The use of blisters and the thermo-cautery are, also, unquestionably, of very great and direct benefit to the gastric disturbance; and so far as the heart is concerned, I have likewise recognized their value frequently in stimulating its contractile power. While this is often true, it is not invariably correct, and occasionally one meets cases of heart-strain and cardiac debility in which blisters and the thermo-cautery remain without obvious beneficial effects upon the heart itself.

In these examples I have hitherto had the best results from the administration of tincture of the chloride of iron, in moderate and frequently repeated doses continued for weeks and months, while the liver was gently stimulated by tablet triturates of calomel, gr. $\frac{1}{4}$ to $\frac{1}{2}$, morning and evening, or oftener. The usual heart-tonics have sometimes proved inefficient; again, they have been evidently useful. I do not approve of the use of digitalis in these cases, except in very moderate doses, combined or not with the iron tincture. If too much digitalis be given, instead of helping the patient it does him harm.

On several occasions, when digitalis has proved to be useless or injurious, I have had very excellent results from caffeine or convallaria. Certainly, the latter drug is more easily tolerated by a sensitive stomach than digitalis is; and whenever the nervous supply of the heart is especially implicated, I believe that I secure more quieting effects from its employment. Among well-known cardiac tonics and stimulants for obtaining temporary good effects, at least, I know of no drug quite equal to coca. Given in the form of wine or fluid extract, it does much at times to restore the heart-muscle to its former tone.[1] Of course, the good effects of any and all treatment will be closely allied with the stage of the disease when it first comes under observation. If the heart-muscle be healthy, with the exception of more or less loss of tonicity or contractile power, its complete integrity may be restored. If, on the contrary, the heart-fibres are already considerably stretched and the cavities dilated, while in some instances the patient may be restored to apparent health for a shorter or longer period, the probabilities are that ultimately renewed distress will be felt and further progress in the disease will take place.

Whenever accompanying the condition of heart-dilatation, be it only very moderate in amount, fatty degeneration has already begun, the outlook is most serious. Even then these individuals may live a number of years, provided no great call be made upon the heart-force. But if efforts, mental or physical, be continued, or if an acute bronchitis become developed through over-fatigue and exposure, such cases often terminate fatally and in a very brief lapse of time. Perhaps a few days or weeks may bring on the fatal ending. In the instances which I have studied I have not felt obliged, except in rare instances, to give narcotics to allay temporarily great pain or dyspnœa. Certainly, in the first stages of heart-strain, when they are less likely to do harm, they are rarely required. Later on, in the midst of a complicating acute attack in the lungs or kidneys, I am very loath to employ anodynes, except in very small doses and at relatively long intervals. I owe this reluctance, doubtless, to the fact that, despite theories to the contrary, and the matured observations of skilled clinicians, I have known great harm to result in my own practice from what I now regard as a *very unsafe* use, especially of opiates. There are times, of course, when a small hypodermic of morphine, combined or not with atropine, will be wonderfully beneficial to the victims of heart-strain or heart-weakness. The cases that I have seen in which these admirable effects were produced were those where there was no complicating acute disorder of another important and closely connected organ, and they were those, also, where the suffering had been occasioned by relatively extreme effort producing a fresh outbreak of symptoms, which were the proof of acute grafted on old cardiac changes.

Under these circumstances, indeed, the introduction of morphine under the skin has often given temporary quiet to the dilated, laboring, and overburdened heart when nothing else could. The safety-line, however, is very narrow; and while one-eighth, one-sixth, or even one-fourth grain of morphine hypodermatically may frequently be of immense service in restoring rhythm and force to rapidly failing heart-beats, a larger quantity will be likely to occasion rapid collapse and death.

From the foregoing study it may be reasonably inferred:

1. There is a class of cardiac disease to which the names of "heart-strain," "heart over-strain," or "weak heart" may be properly given at the present time, and until this class has been more carefully subdivided.

2. In this class are now included cases in which there are no marked physical changes, and in which the symptoms alone indicate cardiac weakness.

3. In many cases the physical cardiac changes are more or less marked, and usually show some dilatation, joined or not with slight or moderate thickening of the ventricular walls, and accompanied or not with mitral or aortic incompetency.

4. There are cases in which the heart is obviously somewhat enlarged, although there never have been any morbid symptoms which showed cardiac weakness.

5. The causes of these affections are numerous; among them, however, prolonged or excessive physical exertion is often, although not always, prominent.

6. In some cases the disorder seems to be one more of neurosal than muscular deficiency, and may affect the function of the pneumogastric nerves, the sympathetic or the intracardiac ganglia.

7. In several instances the causes of cardiac disorder are very obscure or wholly unknown; and in such instances we must admit the existence of a *weak heart* primarily, that is sometimes first recognized suddenly and without premonitory indications which shall enable us to foretell such condition of cardiac debility.

8. Absolute or relative repose, appropriate diet, change of scene, chalybeates, cardiac tonics, counter-irritation, etc., employed judiciously, will do much in most cases to restore real or apparent cardiac vigor for a shorter or longer period.

[1] I have obtained the best effects from the use of Mariani's wine. From personal information given me by this reliable pharmacist, these results are attributable to the excellent quality of the coca-leaves and of the wine which he uses in its manufacture.

What is Conservative Surgical Practice Regarding Gunshot Wounds of the Abdomen?—A correspondent in Georgia writes us: "Will you please decide a question, of dispute through your valuable columns, between another physician and myself? The question is this: 'What is the most conservative surgery of the present day in gunshot wounds penetrating the abdominal cavity—especially a pistol-ball?' He contends that the surgeon would be justified in performing laparotomy and searching for the wounded intestines, closing the wounds by the glove-stitch with catgut ligatures. I contend that the above is not as conservative as to treat with perfect rest and arrest peristaltic action with opium; for we don't know how many intestines are wounded, or how many times the same intestine has been perforated by the ball, and by handling the intestines so much, as would necessarily occur in search of the wounded ones, might be set up violent peritonitis, and possibly enteritis, which would cause the patient to sink." To this we answer that the conservative surgical practice for the general practitioner who had had no training in peritoneal surgery would be that of letting the thing alone. If he had some special experience, opinion now tends to support the operation of laparotomy. When done properly, the handling and exposure of the intestines does not cause peritonitis.

SUCCESSFUL PRIMARY LAPAROTOMY FOR RUPTURED TUBAL PREGNANCY.[1]

By A. W. JOHNSTONE, A.M., M.D.,
DANVILLE, KY.

Mr. President and Gentlemen: On the 8th of last October, with Drs. Kinnaird and Huffman, of Lancaster, I saw a former patient of mine whose perineum I had restored about eighteen months before. Her age is thirty-two, and her family consists of one child, eight years old, after whose birth she had a protracted convalescence with the most intractable pain in the left side. I had been telegraphed for on the 6th, but as I was out of the State did not see her until two days after, when I found her in good condition and expressing herself as having recovered almost completely from the attack for which I was called.

It had consisted of a sharp, sudden pain, while stooping, in the left inguinal region, which, as she expressed it, "felt like something had torn loose." From the account that her physicians gave, the pain was followed by a considerable amount of shock, from which, however, she had entirely recovered, leaving little or no trace in the shape of constitutional disturbance. She was still somewhat tender in the left iliac fossa, and by conjoined touch I I found a mass high up to the left of the uterus, about the size of an orange, which was exquisitely sensitive and obscurely fluctuating. The uterus was pushed slightly to the right, enlarged about one-third, but much firmer than the ordinary pregnant organ. She said that she thought herself about two months gone in pregnancy, but that before the attack for which we met, she had not felt an ache or a pain.

The consultation resulted in our suggesting a laparotomy for an extra-uterine pregnancy; but as we could not be absolutely positive that it was not a cyst, or some encysted hemorrhagic or inflammatory product, it was declined, and we started off on the usual expectant plan of hot injections, fomentations, morphine when necessary, etc. Under this managemnt she did well, and when, somewhere about the 15th or 20th of October, she passed some membranous stuff from the uterus, they began to congratulate themselves that it was only an abortion after all. She had been sitting up for some days, when, on October 27th, the same symptoms returned in force, and being from home again, I did not see her until the 29th. By that time she had again rallied, but there was still a little constitutional disturbance, and the peritoneal tenderness had become general. The mass to the left of the uterus had decidedly increased, but laparotomy was again declined. About four days afterward I dropped in and found her with a clearly defined peritonitis, and as there was still great opposition to operation we decided not to wait longer than one week more before we said positively that the exploration must be made.

On the morning of November 6th, however, the most violent attack that she had yet had set in. When I reached her, at 9 A.M., I found a pulse of 130, temperature 99, but so much pain that she was constantly calling for chloroform, as morphine seemed to have lost its effect. At once we made preparations for laparotomy, and by 11 A.M., with Dr. W. Huffman giving the anæsthetic, and Dr. J. B. Kinnaird assisting, I made a two-and-a-half-inch opening at the usual point for exploring the pelvis, and found that in spite of the adhesive peritonitis the extravasated blood had worked its way pretty generally through the peritoneal cavity. After separating adhesions and getting into the cavity of the mass to the left of the uterus, I found a three months' fœtus lying in a much thickened and ruptured tube. To strip out this torn and bleeding duct from its bed of false and true attachments, ligating what seemed necessary, was the work of only a few minutes. To turn out the clots, wash the peritoneum, and pack it with sponges, took as many more. But on seeing the depression so great I did not deem it safe to prolong the operation to the removal of the appendages of the other side, as had been my first intention. So the stitches were put in, the sponges removed, glass tube applied, wound closed, and patient put to bed in profound shock.

No one who has not tried it can tell with what twinges of conscience I watched that flickering pulse and cold, clammy skin, knowing all the time that had I "taken the bull by the horns" a month sooner all that suffering and frightful hemorrhage would have been saved, and that instead of waiting until 2 A.M. for the first attempt at reaction, it would have come at once.

With the literature of the day teeming with the after-histories of successful laparotomies, need I say anything more about this one than that, with the exception of a somewhat protracted drainage, it is an exact repetition of all the rest. It is only necessary to say that after a tedious convalescence she is now out of bed and gaining strength.

But the one idea it has brought home to me is that I waited too long. For had I followed my judgment and forced the operation when I first saw her, instead of "a scrape through," it would have been a prompt recovery. She would have been saved a month of physical suffering, and I an equal period of regret.

While I believe it to be the first successful primary laparotomy for ruptured Fallopian pregnancy on this side of the Atlantic, still it is nothing but the extension of the work of my old master, Lawson Tait. Do not understand me to say, though, that he would have countenanced the long delay before the operation, for the one great lesson which he has taught the world can be summed up in the single word, promptness. I am sure had she been with us last year instead of watching the successive giving way of the different layers of the tube and discharge of the decidua, that the mass would have been enucleated within the first twenty-four hours, and possibly the necessity of the drainage-tube done away with. This at once almost answers the question, What would I do with extra-uterine pregnancies in general?

Four papers, in the *British Medical Journal* for December 4, 1886, place the various methods side by side, as advocated before the British Medical Association, at its last meeting, by the most earnest champions of each.

I am sure that any unbiassed judge, after reading the whole discussion, cannot help but say that the most rational means of all is to make a clean sweep of the whole thing. What could be more horrible than the condition of the poor creatures that you there see described, who, after having the growth arrested by electricity in some form, or been lucky enough not to die from bleeding before term is reached, still have to go through the terrible ordeal of getting rid of the remains by ulceration. So, without going further into the discussion, I say, most unhesitatingly, that, whether ruptured or not, we should remove it by laparatomy as soon as found. This case of mine, as you see by her previous history, is no exception to the general rule, that Fallopian pregnancies are always sequelæ to some antecedent pelvic trouble. In a conjoint debate before the British Gynecological Society, at its meeting on the 23d of last June, on a paper by Mr. Bland Sutton, on "Menstruation in Monkeys," and one by myself on the "Menstrual Organ," I think we brought out the real explanation of the accident. What I then said on this point was as follows:

"There were two points especially in which I thought we could help each other. I was sure that Mr. Sutton's proving that the epithelium of the tubes is not lost during menstruation was a help to me in understanding Fallopian pregnancies.

"Ercolani had proved that the first uterine change after the fertilization of the ovum was a destruction of the epi-

[1] Read before the Central Kentucky Medical Association, January 19, 1887.

thelium, thus laying bare the adenoid tissue for the formation of the placenta; and I thought that the menstrual denudation was the explanation of the frequency of pregnancy directly after menstruation, and that the fact just shown by Mr. Sutton went in the same line—that is, that under all normal conditions the epithelial lining of the tube protected the adenoid layer from the passing ovum, which was thus forced to enter the uterus before finding a fit place of attachment. But when, from any cause, the adenoid layer is exposed, the ovum is given an opportunity to adhere, and a tubal pregnancy is the result. Thus, the idea that extra-uterine pregnancies are always the result of some preceding pathological change, is given new force." But for the ideas then expressed by Aveling, Tait, and others, I refer you to page 301 of the November number of the *British Gynecological Journal.*

Since that meeting I have seen a good deal of tubal disease, both clinically and pathologically, and it all goes to strengthen the belief that a desquamative salpingitis is at all times an antecedent of extra-uterine pregnancy, and that an impassable stricture is not a necessary factor. While watching the convalescence of this case, I thought, combined with one of tubercular peritonitis (in which there was a doubt before operation as to what the mass of intestines that were bound to the back of the cavity was), I had good material for illustrating the life-saving power of exploratory excision. Had I then had the six-foot intussusception (which behaved so much like an abscess of the pancreas until the operation, ten days ago), I would have been ready to defy a whole America full of sceptics.

But Professor Thomas, by his recent paper before one of the New York societies, has taken the wind out of my sails, and broken the back of the opposition. For as long as Twenty-third Street held firm, and New York laid down the vagina as the only route for relief, the average medical mind was kept as religiously shut as the peritoneum used to be. With this black cap of ignorance hundreds of our American sufferers were let sink into their untimely graves, or, still worse, into the horrors of utter despair. Now, however, it is different, and he who fails to learn anew this lesson of the abdomen is his own executioner. I agree with Professor Thomas fully in his conclusion that the fingers that enter this incision should be guided by a trained brain; and I am glad to say, by the facilities which our country now gives, such an one is at the disposal of almost all patients, no matter how remote. But I must demur to putting in the whole hand; for a brain that cannot find out with two fingers what is the matter ought not, in my opinion, to be allowed to direct any sort of an operation. One of the great secrets of success in abdominal surgery is knowing where to stop; and when you make the opening large enough to admit the hand, the Rubicon ought to be already crossed, and your mind firmly made up to complete. If you do not intend to finish, your aim should be to do as little damage as possible.

Now for my claim to American priority, and I am through. It is based principally on two letters. One of them was from Dr. J. E. Janvrin, of New York, to Dr. J. T. Johnson, of Washington, D. C. As I had been out of the country for some time I had not kept up with the home literature of the subject; so when I was ready to write up this case I wrote to my friend, Dr. J. T. Johnson, for American references; and he, in turn, kindly wrote to Dr. Janvrin, as being the best posted man on the subject, and with the permission of both I read you his reply:

"191 Madison Avenue, New York,
November 24, 1886.

"My dear Doctor: In reply to your note of the 22d, I would say that when I prepared my paper on tubal pregnancy, in August, I was not able to find any recorded cases of the *primary* operation for ruptured Fallopian pregnancy *in this country.* I have not heard of any since that date (except this case of Dr. Johnstone's). I mentioned in that paper the twenty-three cases reported by Tait, and took the ground that if the diagnosis was well made out, the primary operation for the removal of the fœtus and ruptured tube ought to be done. If any cases have been done, and have also been reported, they can be found in the "Index Catalogue" at the Surgeon-General's office. I have spoken to several of our gynecologists since receiving your letter, but have been unable to obtain any information from them. Perhaps it would be well for you to forward this little note to Dr. Johnstone. Very likely his case will prove to be the first operative case (primary) in this country.

"Very truly yours,
"J. E. Janvrin."

The other letter is from Surgeon John S. Billings, of the Surgeon-General's office, in reply to one from myself. He says: "I have not yet arranged my references to 'extra-uterine pregnancy,' so as to be able to definitely answer your question. I enclose herewith, however, references to three cases of the kind you refer to, which may be of some interest." Of these only one was a primary operation for rupture, by C. K. Briddon, published in the *Philadelphia Medical News*, 1883, xliii., pp. 666–668. The case died in forty-seven hours, of shock.

Thus it will be seen that no authentic case of recovery had been recorded up to last August. Since then I can hear of but one other case that has any claim to consideration, and I heartily wish that that had no flaws at which the conservatives could carp, for it was done by my companion and associate, Dr. Jos. Price, of Philadelphia, somewhere about the first of last October. Had he found a fœtus, or had there been no doubt about the tube containing a placenta, instead of a hemorrhage, as some who saw it claimed, Tait would have been vindicated one month sooner, and Price and I would have had an earlier jubilee.

There is nothing that I more heartily dislike than a priority contest, and had it not been for the way in which our teacher has been misunderstood, as well as abused, neither Price nor I would care much about it. But knowing full well that all his disparagement, which has even reached this Society, is merely the dying clamor of his distanced rivals, all his pupils are anxious to give "the new world" an object-lesson from his teaching. And were he here, I am sure Price would be the first to applaud these specimens, and the most positive of all in his agreement with me that Lawson Tait is not only all that his published work would have you think, but for all time he will be proved to be the greatest benefactor that the age has yet produced.

The Medical Board of the French Hospital has recently been organized and the following appointments have been made: Ward service, Drs. J. J. Henna, Menierre, F. A. Lyons, and C. D. Scudder; Dispensary service, Drs. P. Rengifo, E. F. Tucker, and J. E. Newcomb.

The Treatment of Diarrhœal Diseases.—Dr. M. S. Leslie, of Greenup, Ky., is not disposed to regard the antiseptic treatment of diarrhœal affections with as much favor as were the speakers in a recent discussion at the Academy of Medicine. He writes: "While I do not question the value of antiseptic agents in the treatment of these affections, I do question that they are as all-sufficient as the speakers at this meeting seemed to regard them. For a long time I have regarded opiates as very unsatisfactory remedies in the treatment of this malady. But for the past year I have extensively used bromide of potassium with the happiest results, and I have come to regard this salt as the remedy *par excellence* in diarrhœal conditions. The antiseptic bromine element of this medicine may be entitled to some credit for the benefit resulting from its use, but to the sedative properties of the salt is mainly due its curative effects in the therapy of diarrhœal diseases."

Clinical Department.

A RARE CASE OF FRACTURE.

Dr. E. S. Willard, of Fairfield, N. Y., reports the following case: "On the evening of September 15, 1884, I was called to see G—— S——, lying on the roadside intoxicated. He had fallen from and been run over by his loaded wagon. When found, his left ear was nearly severed from the head, numerous bruises and abrasions occurred, the right humerus was broken between the upper and middle third, and *both* clavicles were broken about the middle third. He was removed to his home, several miles distant, and, with the assistance of his family physician, I dressed his wounds and left him, not seeing him again till January following, when he called to see me. Upon questioning I ascertained that union had taken place at all points of fracture, and that he was nearly as sound as ever. He must have been about sixty years of age."

CONVULSIONS FROM IMPACTED FÆCES IN A YOUNG CHILD.

Dr. G. W. Squires, of East Avon, N. Y., writes: "On the 15th I was hastily summoned to see a little girl eleven months old who, the messenger said, was dying in a fit. On my arrival I found the child just recovered from a convulsion, but there was twitching of the muscles and every indication of more convulsions. The thumbs were flexed in the palms, the eyes were wild and squinting. Upon examination I found the abdomen greatly distended, with hard, knotty-looking lumps, which were readily recognized as being in the bowels. The mother made the remark that the child had been 'terribly constipated;' that she had given her as much as three teaspoonfuls of castor-oil without a movement of the bowels; that she had been in the habit of feeding her on potatoes, cabbage, bread, and in fact everything she ate herself. Every few minutes the child would cry out, and bend almost double. I at once ordered injection of warm water and castile soap, and in ten minutes the bowels moved, bringing away a great quantity of hardened scybala the size of hickory nuts; the child immediately felt relieved, and soon went to sleep. At the end of an hour she started up with another violent griping pain. Another injection was immediately given, bringing away more fæces covered with mucus; a few grains of comp. licorice powder was given, and the injections were repeated seven times, each time bringing away less hardened dejections, until the last was of quite natural consistency. The fever-thirst and convulsive symptoms disappeared as if by magic, the child asked for playthings, and was more bright and cheerful than it had been for weeks. The mother told me that the night before the convulsion the child had a severe attack of croup, which was undoubtedly of reflex origin."

TEDIOUS LABOR FROM LARGE SIZE OF THE FŒTUS.

Dr. J. M. Perkins, of Grove Springs, Mo., reports the following case: "I was called on January 7th to see Mrs. J. J. R——, and found her in labor. On examination the parts were seen to be well relaxed. The os was dilated about three or four inches in diameter; the edges seemed very soft and flabby. The pains were regular, but not of sufficient strength to deliver the fœtus. The fœtus presented by the left occipital position. I waited two hours for the pains to increase sufficiently to effect the delivery of the fœtus, but they became no stronger. I then gave the patient one drachm of fluid extract of ergot, and waited until it began to act. I then ruptured the membranes, and let out the liquor amnii, after which the pains began to increase in vigor and come on every five minutes. Everything moved on all right for about one hour and twenty minutes, when the fœtus was born. The cord was around its neck, and about half-way from placenta to fœtus it was tied in a knot like a figure of eight. The child was a very large boy, weighing fourteen pounds. The head measured, in circumference, seventeen inches around occipito-frontal diameter, and was nine inches from ear to ear, over the top of the head. Who can show a larger boy than that from a mother weighing only one hundred and thirty pounds?"

SUPRA-CORACOID DISLOCATION OF THE HUMERUS.

Dr. F. B. Streeter, of Glenn's Falls, N. Y., reports the following case, seen by him in consultation with Dr. R. J. Eddy. The patient, a gentleman of middle age, fell down the stairs in his barn, striking upon his left elbow. The coracoid process was evidently fractured, and the articular head of the humerus was plainly felt above the clavicle, the patient being very thin and spare in person. At the present time he is making good progress toward recovery.

FRACTURE OF THE INTERNAL EPICONDYLE TREATED WITHOUT SPLINTS.

Dr. S. M. Stocker, of Duluth, Minn., writes: "In an article on 'Fractures of the Upper Extremity' which appeared in The Medical Record, December 19, 1885, Dr. Samuel W. Smith recorded a fracture of the internal epicondyle treated without a splint, and with perfect motion of the joint as a final result. I have a similar case to report. I was called Saturday, October 16, 1886, to see Emil N——, a boy twelve years of age, who had fallen to the floor, a distance of two and a half or three feet, while climbing through an open window. I found him in bed, with his left arm resting on a pillow. There was considerable swelling about the internal condyle, but all the motions of the joint were present, though more or less painful. The point of the condyle could be felt three-fourths of an inch lower than normal, and being grasped between thumb and forefinger could be freely moved in an antero-posterior direction. It could be carried upward far enough to give distinct crepitus, but not exactly into place. I carried it upward as far as possible, and endeavored to hold it with compresses and a bandage. Sunday morning, finding everything snug, I did not disturb the dressing. I gave a guarded prognosis, and explaining the necessity of careful watching, I directed the boy's mother to send him to my office Monday afternoon for inspection and renewal of dressing, if necessary. The boy failed to appear, and on the following Friday I visited his mother, who informed me that his arm was not broken, that he could move and use it, and that he was in school. I directed her to send him to me Saturday, one week from the date of injury, for inspection. The dressing I had put on the arm was still there, but was becoming loose. I had left the forearm midway between extreme flexion and extension. Flexion could not be made from this position, but extension could be made through an arc of fifteen or twenty degrees. The point of bone was where I had left it, and could not be moved by a moderate amount of force. On Sunday, the ninth day, I began passive motion, and made it every day until November 21st, when it was discontinued, as all the motions were perfect and painless. The boy was seen at my office during the treatment by various practitioners of Duluth. He was also exhibited at the November meeting of the St. Louis County Medical Society. The gap could be plainly felt, and the diagnosis was confirmed by all who examined him."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 26, 1887.

SOME OF THE LESS COMMON USES OF ANTIPYRINE.

IT is unfortunate that many of the more recently introduced drugs, especially the newly discovered antipyretics, should have received names expressive of only one of their applications, for such a nomenclature is misleading and tends to cause other valuable properties of the drug to be overlooked. This remark applies with special force to antipyrine, which has many uses other than as a reducer of abnormally high temperature, but which, on account of its unfortunate name, is regarded and employed by a majority of the profession as an antipyretic pure and simple. We propose briefly to indicate a few of these other less known therapeutic applications of the remedy.

As pointed out in THE MEDICAL RECORD of September 11, 1886, by Dr. John Blake White, antipyrine possesses a remarkable power in controlling headache from whatever cause arising. The writer found that it relieved this symptom when due to indigestion, loss of sleep, menstrual disturbance, or mental fatigue, and that it was efficacious in uræmic headache and in recurrent attacks of cranial neuralgia. It also acted as a prophylactic in sick headache. This observation of Dr. White received independent confirmation nearly at the same time from a German source. Dr. Ungar, writing in the *Centralblatt für klinische Medicin*, of November 6, 1886, states that he has obtained excellent results with the drug in the treatment of hemicrania. When given at the beginning of an attack, or during the prodromal stage, it usually cut short the affection or so modified its intensity that the patients were able to attend to their ordinary affairs with little inconvenience. In a few cases, he states, antipyrine failed to exert any noticeable effect, and occasionally, even in the same individual, relief would be obtained in one attack and not in a subsequent one. The usual dose employed was fifteen grains.

Antipyrine has also been recommended very highly as a dressing to indolent ulcers. Dr. Bosse (*Berliner Klinische Wochenschrift*) has used it for this purpose, and says that it acts as an excellent stimulant and promotes granulation. The surface of the ulcer is covered with the drug in powder, over this is placed a layer of salicylated cotton, and the whole is retained in place by a tight bandage. The remedy is used only as a stimulant, and after granulation has become well established it is replaced by iodoform.

Another use to which this drug has been applied is as a hæmostatic. Dr. Casati uses it in five per cent. solution externally, and also finds it of value when given internally. Dr. Lavrand has found good results from the administration of antipyrine in epistaxis. The remedy, he says, is certain and prompt in its effects, and much superior as a hæmostatic to the perchloride of iron, and he has succeeded by its use in controlling a nosebleed which had persisted in spite of plugging of the anterior and posterior nares. It is employed for this purpose in a three per cent. solution applied on lint and introduced as far as possible into the nasal cavity.

Some observers have also noted a slight hypnotic action of antipyrine. This effect is not marked, but is still fairly constant. It has been noticed especially in cases in which the drug was given for the relief of headache, and possibly it was simply the result of the cessation of the pain.

These are some of the observations which have been reported of the less common applications of antipyrine, and they will suffice to show that the reduction of temperature is not the only therapeutic effect which can be obtained by means of this valuable drug.

A NEW CHOLERA FUNGUS.

A REPORT of the Commission upon Cholera which was despatched to Spain last year by the conjoined action of the Royal Society, the University of Cambridge, and the Association for the Promotion of Scientific Research, has appeared in the proceedings of the first-named body (*The Lancet*). The commission consisted of Drs. Roy, Graham Brown, and Sherrington, and the report, although "preliminary," contains matter of much importance and interest. Twenty-five typical cases of cholera were examined, either immediately or at a short interval after death, with the result that Koch's comma bacillus was not discovered in the intestinal canal in all the cases. In some this microbe was present in great abundance; in others it was far less conspicuous; while in many undoubted cases, where death occurred before the reaction stage set in, it could not be detected at all. These observations were confirmed by the results of plate cultivations in gelatine and agar-agar. Moreover, it was found that when present the comma bacilli were collected either on the surface of the mucosa or so close to it as to suggest a penetration of the epithelium after death, but in the majority the organism could not be found in the mucous membrane or in any of the tissues or organs. These results, which are directly opposed to Koch's, are considered to be conclusive against the bacillus having a pathogenetic relation to the disease; but it is suggested to be the cause of the premonitory diarrhœa, which is held not to be a mild attack of Asiatic cholera, but only a predisposing condition. Having thus satisfied themselves that the comma bacillus is not the cause of cholera, these investigators similarly dismiss the claims of Emmerich's straight bacillus to that distinction, and also state that they were unable to recognize Klein's straight bacillus in any of their preparations.

After much research another fungus was discovered,

which is believed to be pathogenetic. It consists of granular masses and a delicate mycelium, which could not be stained without difficulty, and was pronounced by Messrs. Vine and Gardiner to belong to the Chytridiaceæ, a class which includes many rapidly growing and virulent parasites of vegetables. The difficulties of its detection may have led to its being overlooked by former observers; while the objection of possible after-contamination is met and refuted. At the same time, it is stated that further investigation is needed, especially in the cultivation of the fungus, before the discovery can be held to be conclusive.

It is, we venture to say, highly improbable that the researches above described will have much weight against the long-continued and careful observations of a trained mycologist like Koch.

REFORMING THE PATHOLOGICAL DEPARTMENT OF THE NEW YORK STATE INSANE ASYLUM AT UTICA.

We are very glad to learn that a serious effort is being made toward the improvement of the scientific work at the Utica Asylum. The late Dr. Gray secured a considerable amount of money for the purpose of equipping a laboratory, and an annual appropriation was made for an imported pathologist to work in it. It has been, however, a case of *parturiunt montes, nascitur ridiculus mus*. We look in vain through the literature of psychological medicine to find any contributions from this Utica laboratory that have attracted notice or even won respectful attention. There are many persons who have accomplished more individually, in the midst of hard professional work, than has been done at the institution in question.

We sincerely trust, however, that the appropriations will be continued, for there is abundant opportunity to use the money profitably and to the credit of the State.

We but express the medical sentiment of the State, however, in saying that some radical change in the management should be made.

MORE ABOUT SPECIALISTS.

The latest contribution to the ethics of specialism is an article by Dr. Morris H. Henry in the last issue of the *North American Review*. The author alludes to articles published by Dr. Morell Mackenzie and Dr. Donkin in the *Fortnightly Review*, and which have been spoken of in these columns. Dr. Henry's view is that of the great majority of physicians. He condemns as hasty and inconclusive many of the conclusions drawn on the subject of specialism in America by Dr. Mackenzie while on his recent visit to this country. His advice is to anyone who may wish to consult a specialist, to talk first with his own family physician, and to follow his advice as to whom to apply. He recognizes that the best preparation for special work is general work. The latter teaches best of all those broad principles which must govern all investigations, and gives the proper instruction in regard to general scientific methods.

Dr. Henry maintains that only those men are entitled to be called specialists, in the true sense of the term, who have laid a foundation by, at least, ten years of general practice, and who have eliminated from their practice all but a certain class of cases, in which they find themselves especially interested, and in the handling of which they have acquired a special tact. The relation of any and every part of the human body to the organic whole is so subtile that one must understand the whole in order thoroughly to understand a part.

Many of our alleged specialists are far from confining themselves to the distinctive fields suggested by their class names. The same tendency is observed in many of our institutions for the treatment of special maladies. In a recent annual report of one of these institutions, there were reported under the head of "diseases of the throat and nose" fifteen cases of acute bronchitis. Doubtless their treatment was right and proper, but we fail to see why they should have been placed in this category. In regard to the treatment of bronchitis, it might be safely assumed that the average physician, though a general practitioner, would not err therein.

We shall have specialists as long as the world lasts. They have secured a position from which they cannot be dislodged. To them is due the increase in positive knowledge in many departments of medical research. Specialists, however, are, contrary to what obtains in the case of poets, made and not born. This making can result only from general experience, and the subsequent narrowing of one's field of work.

RECENT ADVANCES IN ELECTRO-THERAPEUTICS.

Dr. Paul Möbius has collected and reviewed two hundred and six contributions which have been made to electro-therapeutics during the past five years (*Schmidt's Jahrbücher*, 1887, No. 1). Many of these bear chiefly upon electro-physiology, electro-diagnosis, and technique, but a good share are devoted to the showing, by those whom Möbius calls "happy therapeutists," of the beneficent results of the electrical force upon morbid processes.

The unbiassed student of electro-therapeutical work cannot fail to share somewhat the pessimism of the German reviewer, who says, in effect, that no certain progress has been made in our knowledge of how electricity acts in disease, or whether it acts at all. This may perhaps, or rather may certainly, be said, that electric currents have a pain-allaying power, and do relieve a number of neuralgic pains. But as to paralysis we are still in the dark. We know that after the motor paths are broken in brain, or cord, or periphery, there is a process of reparation which follows naturally by certain laws. But do electrical currents influence this process of repair at all? Of this there is as yet absolutely no demonstrative evidence. Some cases seem to begin their improvement with the beginning of electrical treatment; others seem to cease their downward progress under it. But these effects are not uniform, perhaps not even the rule. There is no doubt that paralytics are often bettered by electricity, simply through virtue of its mechanical effects, just as they are bettered by massage and muscle-beating; and there cannot be any doubt of the value of electricity as a mechanical tonic, so to speak. But this is admitting that it has no specific effect whatever. In many functional disorders this mechanical effect comes into play, while in all diseases the psychical element

is most important. It is perhaps through the psyche that electricity acts in a majority of cases. If so, this is no argument against the use of electricity, since the wise physician always utilizes the potent influence of mind in promoting recovery from disease.

There have been brought out some special applications of electricity, some of which still remain to be positively shown are advantageous and effective. One of these is the use of the constant current in urethral and other strictures. Another is the use of galvanism in extra-uterine fœtation, and the passage of very strong currents through fibroids by means of specially adapted electrodes in order to produce their absorption (Apostoli's method). Stein, of Frankfort, has become an apostle of general electrification for the cure of innumerable diseases; while most remarkable of all are the claims of Müller for the use of very weak currents frequently repeated and applied over the seat of the disease. *Leve, breve, sæpe in loco morbi*, is his motto, prefaced to a book in which he announces the cure of such disorders as pseudo-muscular hypertrophy, transverse myelitis, locomotor ataxia, etc. He, with Neftel, Stein, Clemens, Apostoli, must be placed in the category of "happy therapeutists" whose large promises, perhaps, have the value of stimulating hope and energy in their own patients and too credulous practitioners.

A QUESTION OF PRIORITY IN RAPID DIVULSION OF THE VOCAL CORDS.

It has been our pleasant duty from time to time to correct in these columns the misapprehensions of some of our transatlantic brethren concerning the originality of certain methods of diagnosis or therapeutic measures which they have brought forward with the claim of priority. We have shown in several instances that these methods, however original they may have been with the authors, as far as they themselves were aware, were not new in this country, and that to American physicians was due the credit of priority in their invention and execution. We are now again called upon to dispute the claims of an Italian physician to priority as regards the operation of rapid divulsion of the vocal cords for the relief of laryngostenosis.

In a communication presented at a meeting of a provincial branch of the National (Italian) Association of Communal Physicians, held in Faenza, Dr. Peruzzi related the following case (*Il Raccoglitore Medico*, December 10, 1886): The patient was a man, thirty-four years of age, who had acquired syphilis some time previously, and for the past seven or eight months had noticed a gradual weakening of the voice, difficulty in breathing, and pain in the throat. Laryngoscopic examination showed the vocal cords united along almost their entire extent, and moving scarcely at all in attempts at phonation. The pharynx was red and covered with granulations. The diagnosis was made of laryngeal stenosis with sclerosis of the vocal cords, following upon syphilitic ulceration.

The patient was put upon antisyphilitic treatment, but the suffocative attacks became so threatening that it was determined to operate. On the morning of October 22, 1886, laryngotomy was performed by Dr. Loreta. Then a dilator, such as is used in cystotomy, was passed into the wound and through the small aperture remaining between the vocal cords. The blades of the dilator were then separated in the direction of the cords, and the latter were thus torn apart. Finally a tracheotomy tube was inserted. Three days later the cannula was removed, and a rubber catheter passed through the rima glottidis, and this was repeated every subsequent day, a larger tube being used each time. On the twelfth day the tracheotomy tube was permanently removed, and the patient soon recovered his normal voice and was definitely cured of the stenosis.

The author of the paper emphasized the originality of the operation, and stated that he had never read of any recorded instance of instantaneous dilatation or divulsion of the vocal cords, nor had he been able to learn from those acquainted with the literature of the subject that such an operation had been performed. The importance of the operation as a means of cure was also dwelt upon, since, in addition to the great saving of time, the ultimate results should be better if, as was held by many, a rapid stretching of fibrous tissue induced fatty degeneration and a consequent loss of retractile tendency.

We confess we are hardly prepared to admit the claims to originality in this operation, although we do not doubt that the writer was correct in his assertion that he could find no recorded case of instantaneous divulsion of the vocal cords. Most of the text-books on laryngology merely refer to rapid divulsion, but give no directions for its performance, and the instruments of Mackenzie and Navratil have been used chiefly in conjunction with the passage of catheters to hasten somewhat the progress of gradual dilatation. Yet they could be employed for the purpose of effecting instantaneous separation of the adherent cords, and doubtless have been so used.

But the identical operation of rapid divulsion has been performed by Dr. Joseph O'Dwyer, of this city, and was reported in THE MEDICAL RECORD of June 5, 1886, more than five months before Dr. Loreta operated on the case above referred to. The patient was referred to Dr. O'Dwyer for the purpose of removing the vocal cords on account of bilateral paralysis of the abductor muscles. She had worn a tracheal cannula for two years. Examination showed almost complete occlusion of the larynx from syphilitic adhesions, and the operator enlarged the tracheal opening, broke up the adhesions thoroughly, by inserting a pair of dressing-forceps and withdrawing them open, and then inserted a tube. We understand that he subsequently removed a portion of each cord, as there was shown to be complete paralysis of the abductors, as well as stenosis.

We do not assert that this was the first instance of rapid divulsion of the vocal cords, for others may have performed the operation many times. But certainly Dr. O'Dwyer's case antedates that of Dr. Loreta, and we feel justified, therefore, at least as far as these two instances are concerned, of claiming for America the credit of priority over Italy in the operation of rapid divulsion of the vocal cords for the cure of laryngostenosis.

THE MICROCOCCUS OF TUMORS.

THE belief that some forms of tumors are caused by micro-organisms has long seemed very plausible, and diligent efforts have been make to discover these. So far, however, among tumors, only the fungus growth known as actinomycosis, a growth presenting some of the clinical appearances of a maligant tumor, has been discovered to be caused by a parasite.

Dr. Luigi Manfredi, while working in the Laboratory of Cantani, at Naples, discovered quite recently a minute organism which possessed extraordinarily specific and virulent properties. It was obtained from the sputum in two cases of pneumonia, each being a sequel of measles, and running a rapid and highly maligant course. The pneumococcus of Friedländer was observed in each case also. The new organism is oval in form, often appears as a diplococcus, and is about 0.5 mm. in diameter. It has a characteristic method of growth, which is described by Manfredi in his original article (*Fortschritt der Med.*, No. 22, 1886).

A large number of inoculation experiments with pure cultures were made upon dogs, rabbits, guinea-pigs, mice, and birds. With the exception of the last named, which seem to die from blood-poisoning, Manfredi found that the micrococcus uniformly caused one and the same pathological condition. This consisted of the deposit of gray, or grayish-yellow, nodules in the parenchyma of organs, especially of the spleen and lymph glands. The lungs showed in addition the characteristic marks of a more or less intense pneumonia. The nodular masses belong to the type of the granulomata, or infectious granulation tumors. They consist of masses of newly formed cells without blood-vessels, and they begin gradually to become cheesy, to soften in the centre.

The infective granulomata include tubercle, lupus, syphilis, glanders and farcy, leprosy, and actinomycosis. The parasite described by Manfredi produces pathological changes somewhat similar to those of the diseases of the class mentioned.

THE MEDICAL STANDARD is the name of a new medical monthly recently started in Chicago, and published by G. P. Engelhard & Co. It is edited anonymously and with considerable pungency. Regarding the recent interest developed in hepatic surgery, it says: "It is a singular illustration of the influence of cliques on medical science that when the very principles on which the present surgical practices are based were first enunciated by Dr. W. A. Hammond (*Virginia Medical Journal*, October, 1879), they were, although supported by the authority of Dr. Marion-Sims, denounced and ridiculed. Dr. Hammond claimed: That hepatic abscess was much more frequent than was generally suspected, and often passed unnoticed, the symptoms being ascribed to other co-existing diseases; also, that the operation of aspiration was unattended by any danger, and it alone often produced good results on the hepatic and cerebral affection giving rise to the symptoms; that hepatic abscess and other hepatic affections were often of a trophic nature and of cerebral origin.

MILK IS NOT A GOOD THING TO GIVE IN DIABETES.—This seems to be the prevailing medical opinion just now.

News of the Week.

DEATH OF DR. FENNER HARRIS PECKHAM, OF PROVIDENCE, R. I.—Dr. Fenner Harris Peckham, one of the oldest and best known physicians of Providence, died Thursday of chronic Bright's disease, from which he had suffered for nine years. He was born in Killingly, Conn., January 27, 1820, his father being an able and noted physician of extensive practice. After graduating at Yale Medical College in 1842 Dr. Peckham began his medical practice at Killingly Hill (now Putnam Heights) and removed to Providence in 1852. He was twice chosen president of the Rhode Island Medical Society. He has contributed to literature several valuable addresses and monographs on special subjects, chiefly, however, in the department of medical research. During the civil war he served with distinction as a surgeon, first with Rhode Island regiments, and afterward as surgeon of the board of enrolment of the second Rhode Island district. He leaves a wife and six children. Dr. F. H. Peckham, Jr., to whom in 1878 he relinquished the more arduous duties of his profession, was his only son.

NEW HOSPITAL BUILDINGS ON RANDALL'S ISLAND.—The Commissioners of Charities have secured an appropriation of $25,000, and a new pavilion hospital will be erected this summer.

THE DISTINGUISHED ITALIAN OPHTHALMOLOGIST, PROFESSOR MAGUI, died at San Remo on February 2d. He was not only a doctor, however, but a senator and a party leader.

A DIPLOMA MILL IN MAINE.—The *Boston Herald*, of February 11th, contains an account of the manner in which one of its reporters obtained a degree of M.D., from the "Druidic University of America, State of Maine Branch." The "University" is situated in the city of Lewiston, Me., and occupies a two and a half story wooden building, which is ornamented with the sign of "Dr. Samuel York, Druidic Physician." The reporter represented himself as a young man who wished to settle in the city of Mexico, and there practise medicine in all its branches. With many assurances that the college did not sell its diplomas, the proprietor exchanged a matriculation ticket and a most elaborate diploma for a small amount of money, which was said to cover cost of printing and other expenses. The aspirant was also put through some very farcical examinations, and given some equally absurd instruction, the whole transaction covering some six hours' time within three different days. The *Boston Medical and Surgical Journal* says that the Maine Legislature is taking steps to repeal the charter of the Druidic University.

MEDICINE IN SOUTHERN CALIFORNIA.—A correspondent writes us that San Diego, and perhaps some other places in Southern California, are hot-beds for homœopaths, eclectics, and irregular regulars, *i.e.*, "regulars" who advertise as electricians, etc. We learn that a county society has been organized and an attempt made to collect into it the best elements of the profession. We wish it success.

Insane Asylums and Politics.—The House Committee investigating the management of the Indiana Insane Asylum has proved by several of the attendants that there was maggoty butter in the asylum in July, as charged, when sixty pounds of it were thrown into the sewer just before the committee visited the institution, and that such butter was on the tables in October last. It was also proved by a witness that a drove of hogs was received at the asylum, said to be from Dr. Harrison, the President of the Board of Trustees, which as soon as he saw he found were suffering from cholera; that some of them died from that disease, and that the witness killed hogs for the tables from the pen in which some of the animals were lying dead. These were the charges made by the Civil Service Reform Association.

Removal of the Ovaries for the Cure of Epilepsy.—Dr. J. Schramm reports two cases in which he has removed the healthy ovaries for the relief of epilepsy. Both cases were cured—at least, no fits have occurred since the operation, over a year ago.

The Medical Department of the Army.—The U. S. Senate and House have passed the bill establishing the order of promotion in this branch of the service. The measure provides that assistant surgeons of the army who have served twenty years shall be appointed to the office of surgeon, with the rank of Major, to date from the completion of such service. The service is to be estimated, as is now done in computing service for longevity pay, except that service under present commissions is to be counted from the date of the commissions. No assistant surgeon, however, can be promoted under the act until he has been examined and found qualified for promotion by an examining board. The bill also provides that the whole number of officers in the medical department shall not be increased under its terms.

The Emigration of White Blood-cells.—Dr. T. Wharton Jones, to whom belongs the honor of first discovering the amœboid movements of the white blood-cell, asserts most positively that it does not wander from the blood-vessels, as Cohnheim claimed. We do not find, however, that Dr. Jones brings forward any evidence to offset the observations of Cohnheim.

An Epidemic of Small-pox is threatening Australia, more particularly New South Wales.

Castration and Spaying.—The term castration has been incorrectly applied to the removal of the ovaries. The term "spaying" is objectionable to the spayers, as conveying in too plain English the significance of the term to the spayee. "Spaying" is very good English, however, and will answer the purpose quite as well as oöphorectomy.

A Medical College for Women is to be established in Cincinnati. Our country is already tolerably rich in these institutions, which, however, are not particularly rich in themselves.

The Death of Professor Johann Rudolph Ranke, of the University of Groningen, is announced. For the last eighteen months he had suffered from the effects of blood-poisoning, which had caused him continual severe pain; but he stuck most heroically to his work to the last, teaching from his bed students who were about to present themselves for examination, and, on days when he was somewhat better, going in a bath-chair to the university or hospital. Only three days before his death he performed an important operation.

Politics and the Indiana State Board of Health—The pernicious influence of partisan politics upon the conduct of State medical institutions, health boards, etc. is illustrated apparently in Indiana. The *Fort Wayne Journal of the Medical Sciences* says: "We learn that some amendments to the law under which our State Board of Health is organized have been recommended to the Legislature, and we sincerely hope that they may be passed. One provision is that the State Board shall be consulted in the appointment of County Secretaries, or rather County Health Officers. This is a very important amendment, and should be passed at once. As the law now is the County Commissioners appoint the County Health Officers, and they generally appoint some one who can render them the best and the most valuable service at the next election, and not as to his ability as a sanitarian or qualifications as a health officer. The Health Officers generally appointed are third-rate ward politicians.

Deaths of Prominent European Physicians.—To the announcement of the death of Professor Carl Schroeder, made last week, we regret to have to add that of the death of Professor T. Gallard, widely known as a gynecologist, and of Dr. Raige-Delorme, a prominent physician, medical journalist, and editor.

The "Practice Limited" Rule.—"One of the most absurd of the decisions of the Judicial Council of the A. M. A. is the practice limited pronunciamento." So says the *Weekly Medical Review*. We ventured to make a similar criticism some time ago, and are pleased to observe that our judgment has taken its starry way westward—skipping Chicago.

Death of Dr. W. S. Little.—Dr. W. S. Little, the eminent Philadelphia oculist, died at Aiken, S. C., February 18th, after a long illness.

THE REASONS WHY THE LEGISLATURE SHOULD PASS THE NEW MEDICAL BILL FOR THE STATE OF NEW YORK.

The following memorandum has been prepared in behalf of the pending bill to codify the medical penal law (Assembly 129, Senate 45). The opposition this year seems to be led by one eclectic practitioner, who on his own account is sending out postal cards to instrument-makers and others, asking their aid. The eclectics as a body appear to assent to the bill. It can only fail by the apathy of those who have approved it. Every one interested should communicate his views to his Assemblyman and Senator.

Memorandum of Reasons why the Legislature should pass the Bill, entitled "An Act to Regulate the Licensing and Registration of Physicians and Surgeons, and to Codify the Medical Laws of the State of New York;" being Assembly Bill 129, *and Senate Bill* 45.

It is purposed to set out (1) the history of the bill; (2) who favor and who oppose it; (3) its scope as compared with existing law, and (4) the arguments that have been adduced for and against it.

I. History of the Bill.—At present, the highest standard of license to practise medicine in this State is a diploma from a chartered medical school empowered to confer the degree of Doctor of Medicine, and it was held, in a comparatively recent case, that a diploma purchased from the president of such a school was a valid license, although signatures upon it were forged or obtained by that officer's misrepresentation. There are some schools that require earnest work, tested by careful examination of all candidates for their degree, and others that graduate matriculants after merely nominal compliance with the prescribed terms of preparation, while still others are incorporated solely to sell diplomas. As a license, the diploma of the poorest incorporated school is as good as that of the best. In order to mend this evil, an effort has been making for several years to establish a uniform standard of license, by creating a State board of medical examiners. This effort has failed hitherto, because of the impossibility of harmonizing opposing interests in the organization of the proposed Board. The law recognizes, by having incorporated them into separate societies, three classes of practitioners of medicine. These are the regular physicians, as they call themselves, or the old school or allopaths as they are called by the two other classes, who have taken for themselves the names of homœopaths and eclectics. Roughly speaking, there are about 6,000 regular physicians in the State, 1,500 homœopaths, and 600 eclectics. Upon ordinary principles of representation, the regular physicians maintained that each of these classes should be entitled to membership in the proposed board only in proportion to its numbers. The homœpaths and eclectics demanded either several boards (which would imply the very evil to be remedied, a variable standard of qualification) or an equal representation for each class on a single board, arguing that they, under the plan favored by their opponents, would cease to exist as separate schools.

But although the various bills to create examining boards failed, all parties in interest were substantially agreed that the existing penal law should be amended. For this purpose a bill was drafted in 1885 (Assembly Bill No. 820), which being introduced into the assembly by Mr. Van Duzer, on April 22d, passed that body. Introduced by Mr. Robb in the senate (Senate No. 419), it would have passed except for the lateness of the session. In 1886, the experience was reversed; the bill, after careful revision, was introduced by Dr. Craft in the assembly (No. 903), on April 7th, and by Mr. Connelly in the senate (No. 485), on the same day. It passed the senate and failed to reach a vote in the assembly.

The present bill, introduced in assembly by Mr. Hamilton, and in senate by Mr. Connelly, has been specifically approved by the State Societies of both regular and homœopathic practitioners, which are bodies made up of permanent members and delegates from County Societies, representing about fifteen-sixteenths of the whole number of legally qualified physicians of the State. It is understood, also, that at least one eclectic society has approved the bill, and certainly no representative of such a society has appeared to oppose it before the committees having it in charge. It seems, therefore, not unfair to infer that the majority of the eclectics assent to the measure, and it may be reasonably asserted that

II. The friends of the bill are: (1) All physicians desirous of maintaining some standard of professional learning and suppressing charlatanism, and (2) all private citizens who believe that the care of life and health should be entrusted to educated, rather than to ignorant men, and that none should be permitted to attempt the cure of human infirmity who are unfitted by education to write a death certificate, or recognize the presence of a contagious disease.

Its opponents are: (1) All men who honestly believe that the State should not care for the public health, or enact sanitary laws, or inspect steam boilers or provisions, or undertake any similar duty, but no intelligent or consistent argument from this extreme *laissez faire* standpoint has yet been made before any committee; (2) all who sincerely or ostensibly believe in witchcraft, voudoo, occultism, and the various forms under which ignorance, and craft batten on delusion.

III. The Scope of the Act as Compared with Existing Law.—This has been already shown in an article reprinted from The Medical Record of January 8, 1887, and sent to every member of the Legislature. The purpose of the act is (1) the regulation of the licensing and registration of physicians, and (2) that which is above all things desirable in penal legislation, the substitution of one statute for several. The bill is chiefly a codification of existing law, as will appear from the following analysis.

Section 1 forbids a minor or unlicensed person to practise medicine. This is the law now (see Laws of 1880, ch. 513; Penal Code, section 356, and compare Rev. Stat., pt. 1, ch. 14, tit. 7, sections 16, 17, 18, and 20 for the old law).

Section 2 prescribes the qualifications of a licentiate. It makes no change in the law beyond raising the age for beginning study to eighteen from sixteen, and requiring greater particularity in the endorsement of diplomas (see R. S., pt. i., ch. 14, tit. 7, sections 8 to 15, inclusive; Laws 1872, ch. 436; Laws 1880, ch. 513; compare Laws 1836, ch. 532).

Section 3 provides for registration, making no change in the law beyond prescribing forms by which to prevent careless and improper registration of unqualified persons (see Laws 1880, ch. 513).

Section 4 provides for new registration by mail of a registered practitioner removing to a new county. The purpose of the registry law is to have a list of licensed practitioners in every county. At present every registration must be made in person; this change makes the law effective and imposes no hardship on the practitioner (see Hilliard *vs.* State of Texas, Appeals, 69, laying down the same rule as our courts have followed in unreported cases).

Section 5 limits the time in which persons claiming to be licentiates under the law of 1880 and prior acts may register. There are probably few, if any, such persons, as all such practitioners have had already six years in which to register.

Section 6 defines the practice of medicine and forbids the improper assumption of the title Doctor of Medicine. Various instrument-makers having expressed a fear that their business might be included in the terms of the definition, the friends of the bill agreed to strike out the whole of the section except the last sentence, prohibiting the unauthorized use of the title M.D., which will be incorporated in Section 7. This meets the only objection of any force, and leaves the courts to decide in each case whether a defendant, in view of all the facts, has practised medicine, thus preserving the present law without change in this regard (see Smith *vs.* Lane, 24 Hun., 632).

Section 7 enumerates a number of offences, all fraudulent in their nature, that are now scarcely cognizable by the criminal law, viz., perjury in registration, counterfeiting, buying, selling, and altering diplomas, or practising under diplomas forged or bought, falsely personating another practitioner, and practising under an alias, or without registration, or after conviction of felony. The present law only punishes practising without a license. It was intended to punish false swearing or registration, but falls short of so doing by defective phraseology (Laws 1880, ch. 513; Penal Code, section 356).

Section 8 provides civil actions against unlicensed practitioners. The reason for this is twofold. In civil action against an impostor with papers purporting to be diplomas of a foreign university, it may be necessary to issue a commission to take testimony, and this can not be done in a criminal case by the prosecution. Second,

experience shows that merely to deprive an unlicensed practitioner of an action for services only makes him demand fees in advance; therefore an action against him to recover money paid is given to the patient. This is new (compare Rev. St., pt. i., ch. 14, tit. 7, and Laws 1830, ch. 126).

Section 9 exempts from the operation of the statute the persons now exempt and also dentists in their specialty, officers of hospital staffs, and physicians attending individual cases but not regularly practising in a county in which they are not registered.

Section 10 repeals specifically by title every act *in pari materia*, thus avoiding any question that might arise as to repeal by implication, and completely codifying the penal medical laws.

IV. The Arguments For and Against the Act.—Having shown the scope of the measure and that it is substantially a codification, or reduction of several incoherent statutes to one simple act, it only remains to cite and refute the arguments brought against it in committee during the last three years. These are:

1. The bill is unconstitutional and an infringement of personal liberty.

2. It will, if enacted, drive out of practice many persons who, although confessedly ignorant in medical science, have yet occult, mysterious, or even God-given powers whereby they effect cures where the physician's skill has failed.

3. The measure is in the interest of limiting competition by reducing the number of practitioners.

These three misstatements of fact constitute but one argument, to which the simple answer is that:

The bill is not unconstitutional, because (1) it does not infringe human liberty, unless the public school system, the civil service system, and every system requiring educational qualifications of candidates for certain privileges are such infringements, and, therefore (2) it does not prevent any class of persons as a class, unless the ignorant are to be so regarded, from practising medicine or forbid the practice of any system or specialty. In this respect it does not change existing law. (3) It is not to be upheld for one moment on the ground that it will pecuniarily benefit physicians as a class. Physicians approve of it, as lawyers approve of examinations of attorneys before admission to the bar, because it is to the advantage of the reputation of the profession, as well as for the public benefit, that doctors should be educated in medicine.

The true reason of such laws is thus stated by the revisers of the New York Statutes (R. S., 2d ed., vol. iii., p. 526, note to pt. i., ch. 18, tit. 3): "The uniform experience of every civilized country has shown the wisdom and policy of regulating the practice of the healing art *so as to secure the community* against the impositions of ignorance and quackery. The profession of physic and surgery is one of the very few employments which cannot with safety be left by the Government exclusively to individual sagacity and private interest, to determine the qualifications of its practitioners."

In this State the courts have uniformly spoken in the same spirit. Such laws have been always upheld as constitutional from the time of *ex parte* Smith (10 Wendell, 449) to the present moment. The enactment of the law of 1844, which the opponents of this bill would gladly restore, was characterized as the triumph of quackery (Bailey *vs.* Mogg, 4 Denio, 60). Judge Cooley says: "No one has any right to practise law or medicine, except under the regulations the State may prescribe (Cooley on Torts, pp. 289, 290). The Supreme Court of the United States has affirmed the right of a State to regulate the practice of professions (Bradwell *vs.* Illinois, 16 Wall., 142); the courts have so held in Massachusetts (Hewitt *vs.* Chavier, 16 Pick., 353), in West Virginia (State *vs.* Dent, 25 W. Va., 1, an exhaustive opinion), in Minnesota (32 Minn., 324), in Missouri (10 Mo., 591), in Illinois in several cases, and, in short, in every State where the question has been raised. No case can be cited to the contrary.

If the bill forbade the practice of medicine by any class of people, as a class, or otherwise than according to a prescribed system, it might be open to the charge of unconstitutionality, but it does not. The sophistry of its opponents, by which some honest men have been deceived, consists in their false assertion that the act will have such an effect. In fact, however, any person having complied with the present statutory requirements as to study and examination, which it must be remembered this act does not change, may practise as he pleases, and as his honest conviction dictates. He may make his diagnosis by clairvoyance, if he has that gift; he may cure by the rites of voudoo and mumbo-jumbo, by magnetic passes, by Indian medicine methods, or, if he prefer to be a specialist in Chinese practice, by sounding the tom-tom and hewgag till the evil spirit flies with its hands over its ears; and, if he believes himself possessed of greater powers of supplication than his fellow man, there is nothing in the bill to prevent him from praying, so long as his patients consent to be preyed on. He may be liable civilly for malpractice under the common law, on account of such idiosyncrasies, or, perhaps, even criminally for manslaughter; but he will not be liable under this bill as an unlicensed practitioner.

"But," say the opponents of the bill, "it comes all to the same thing, for men who have studied medicine will do none of these things, and the bill discriminates unfairly against the ignorant, *ergo*, it operates against a class."

Here at last is the issue clearly defined. Let it be stated in the words of our adversaries. In 1883 they presented a great petition and memorial to the senate asking the repeal of the law of 1880; they circulated the memorial again last year. It contained this statement, noteworthy in the nineteenth century and a land of public schools:

"This law deprives from practising within this State persons who are gifted with the power 'of healing by the laying on of hands' through the presence and imparting of vital magnetic force and otherwise.

"Some of these powers are natural to the practitioner and cannot be imparted nor increased by, but are more LIKELY TO BE DIMINISHED OR IMPAIRED BY, THE COURSE OF STUDY REQUIRED BY THE MEDICAL COLLEGES."

There is the frank confession of the handful of opponents of a measure, approved by the representatives of over seven thousand intelligent physicians, that their methods are such as no educated physician would adopt. They have made their own issue and cannot escape it. Every one who votes on this bill upon arguments made in committee, must take his stand on the side either of intelligence or of gross ignorance or brazen imposture.

But, finally,

V. If there be any one who is willing to let everybody practise medicine regardless of educational qualification, either because he believes in the efficacious work of the unlicensed, or honestly thinks the State should not interfere in such matters, let him remember that by the striking out, as above noted, of Section 6 from the bill as originally introduced, the law as to unlicensed practice is not changed, except in so far as civil actions are provided for; *and, therefore, if this bill fails the present law will still punish unlicensed practitioners, while those to be benefited by its failure are the felons, forgers, and impostors mentioned in Section 7.*

All of which is respectfully submitted.

W. A. Purrington,
Counsel of the Medical Society of the County of New York.

An effort is being made by the Kings County (N. Y.) Society to place cocaine among the list of poisons.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, February 17, 1887.

A. JACOBI, M.D., PRESIDENT, IN THE CHAIR.

THE PRESIDENT delivered the remaining portion of his inaugural address, in which he dwelt chiefly and at some length on the baneful influence of professional advertising in the newspapers. "What must be prevented is the appearance of reports of striking operations or rare cases which cannot be possibly of interest or a source of instruction to the public at large."

DR. C. L. DANA then read a paper on

SPASTIC ATAXIA, FUNCTIONAL AND ORGANIC, AND THE COMBINED SCLEROSES OF THE SPINAL CORD.

He described a group of symptoms forming a new spinal disorder, and thought that the anatomical basis in typical cases was a sclerosis of the three long-fibre systems of the cord.

The discussion was opened by DR. M. ALLEN STARR, who thought that a thoroughly satisfactory name for the disease described by Mr. Gowers and Dr. Dana must still be looked for. The cases were not all ataxic, nor were they all paraplegic, and the term spastic ataxia was subject to the same criticism which Dr. Dana had entered against the name given by Mr. Gowers.

With regard to the anatomical name, "fascicular sclerosis," the term fascicular should not be accepted, because the lesion was not exclusively fascicular; the sclerosis was rather diffused, and did not involve any particular fasciculus throughout its entire course. In the area of sclerosis there was, as Gowers has said, a very great variety of appearances.

The distinction between locomotor ataxia and combined sclerosis was not a clear one, and the clinical picture of combined sclerosis must be further extended; it was still somewhat hazy, and therefore any contribution toward clearing up the picture was valuable.

DR. G. W. JACOBY said that the remarks made by Dr. Starr had strengthened him in his ideas of this disorder. He did not think that much would be gained from clinical pictures, as from them we were working very much in the dark.

Cases of tabes occurred in which the lateral columns were primarily affected, and the posterior columns secondarily, and *vice versa*, but whether these could be diagnosticated was exceedingly doubtful. It seemed that the majority of the cases of spastic ataxia were really tabes with secondary spastic symptoms, and that the spastic cases with secondary tabetic symptoms were much rarer.

DR. E. C. SEGUIN fully agreed with what Dr. Starr and Dr. Jacoby had said as to the departure in pathological anatomy, in this disease, from the typical fascicular degeneration. In the specimens exhibited by Dr. Dana there were deviations from the typical degeneration of the posterior columns and the pyramidal tracts. It seemed to him that the sections belonging to Dr. Hammond's case presented a sclerosed appearance of nearly two-thirds of the cord, including the lateral columns and a part of the anterior columns.

He then submitted the following epitome of one of his own cases, in which there was a post-mortem examination. A woman, fifty-seven years of age, who had suffered from gastro-intestinal and hepatic derangements for ten or twelve years, first had numbness and awkwardness in both hands in 1879, which was temporary. In the autumn of 1880 she was very well and active, and was much in society. In November she had paræsthesia, and felt as if tangled strings were drawn under her toes. No actual numbness. Found it difficult to raise the feet. Paresis of feet and legs increased, with only slight numbness. Hands and arms normal. In the autumn of 1881 there was a rapid increase of the paresis, and numbness extended to the waist. Walking was slow and difficult; legs stiff in the moving, and disposed to jerk; œdema of the feet and legs in the evening. Within the last two weeks she has frequently lost her legs in bed (anæsthesia), and micturition has been very slow; fingers numb, hands weak and awkward; back painful. Has a constriction band above the waist. No head or eye symptoms. No tenderness of spine. Slight anæsthesia of fingers; they are awkward and feel queer, and are ataxic. Pupils normal; legs paretic. Great increase in reflexes at sole, and at knees; legs somewhat tetanoid; slight sensory symptoms, but no fulgurating pains. Later, more complete paresis; whole body inclined to stiffness; bedsores; œdema of the legs, hands, and face; urine contains a slight quantity of albumen, but no casts; death. Examination of the spinal cord showed sclerosis of the lateral columns extending to the extreme lateral parts of the cord with degeneration changes, and rather irregular in distribution at different levels. The ascending cerebellar fasciculus was affected in some sections, but not in others.

The case apparently belonged to Dr. Dana's second group of spastic paralysis plus sensory symptoms.

DR. W. R. BIRDSALL thought that in attempting to classify many of these cases, while we might be able to separate them, we were able to find a certain number which resembled each other so much that a great many subdivisions could be made, and it becomes questionable whether they were not subdivisions which resulted from various degrees rather than from distinctive types of disease. There was, perhaps, a tendency to attempt to group these cases into distinct diseases, whereas they simply represented variations in type of a general condition, that may affect one column or one particular tract and produce certain symptoms in some cases, while in other cases the disease invades other areas to a little greater extent at different levels transversely in the cord. The symptoms resulting from these variations may be quite marked, and still be due to a process which will hardly bear separation. Gowers, in his attempt to separate the cases of chronic cord trouble, had used the term ataxic paraplegia in distinction from spastic paraplegia, making this difference, that in the spastic paraplegia there were exaggerated reflexes, absence of sensory disturbances, and absence of ataxia; whereas, in ataxic paraplegia there was the same group of symptoms, with the addition of ataxia, and the sensory disturbances do not bear a prominent portion. In most cases of combined sclerosis, sensory disturbances are quite common, as in Dr. Dana's cases, and Gowers has taken pains to explain why certain symptoms are absent, etc. But in making the classification from a clinical standpoint, we cannot attach it to any particular type of fascicular degeneration, as it has been shown that these cases exhibit varying changes in the cord at different levels. There could be no question of the advantages in closely grouping these cases from the standpoint of comparison, but it seemed to him, however, that neurology had made sufficient advancement to prevent making too exact typical forms of disease to fit symptoms into. He made these remarks without reference to the paper of the evening or the remarks that had been made in the discussion.

DR. STARR said he should not be willing to have it understood that he indorsed the diagnosis of combined sclerosis in the specimens from Dr. Hammond's case.

DR. N. E. BRILL said he could not take the ground that there was a general disease which we call sclerosis, and then out of this attempt to make a special group of cases, where this general disease involved special systems. Given a general pathological process, such as sclerosis, it was well known that certain tracts were more vulnerable than others, of which the chief example was the posterior columns. But the process involved other tracts, although how it did so was not known. His idea

of the cases presented by Dr. Dana was that they belonged to a special group of sclerotic cases, and that they involved special classes of nerve-cells and fibre systems in the cord.

The President said he could imagine that sclerotic troubles were propagated along the line of blood-vessels. Not many years ago an anatomist published a pamphlet on the smallest blood-vessels of the spinal cord, and illustrated what was proved by injection, that there were much smaller and more extensive and delicate vessels than had been laid down in text-books up to that time. These observations had proved that there exists a very intense vascular communication between the fasciculi, and if that be so, he could well imagine that a diffuse inflammatory process would spread along the line of the smallest blood-vessels and the interstitial tissue, binding them together. That would explain why the forms of spinal-cord disease were so much mixed.

Dr. Dana accepted the criticism of the name made by Dr. Starr. With regard to the pathology of the disease, he had not endeavored to lay down anything very positive concerning it. With regard to the disease being a combined fascicular sclerosis, he would mention that Strümpell had reported another case in which he says that this disease or spastic ataxia has typical post-mortem showings, which Dr. Dana referred, in the main, to these three columns. Strümpell insists most strongly that it is a primary typical form of disease. While that might be true, Dr. Dana's view was that they were liable to extend into other parts.

As to some of the cases referred to, they could not be discussed without bringing in their individual peculiarities, and with regard to progress of the disease from one strand to another, Dejerine had published a case in which he thinks the changes have taken place by means of lepto-meningitis. Dr. Dana, however, thought that all writers agreed that this was not the way in which they were transferred. It seemed to be rather a primary change in these strands, or else it started from a rather diffuse myelitis, and was to some extent secondary. As to Dr. Hammond's case, which gave the symptoms of spastic paraplegia, it showed that some of these cases have a different pathological anatomy. With reference to the pathological findings, while they were as Dr. Starr had said, it seemed to him that there was sclerosis in the lateral columns, and that was also the opinion of Dr. Spitzka, who had seen the sections.

AN AMENDMENT TO THE BY-LAWS

was adopted which abolishes the privilege of commuting for annual dues.

The Academy then adjourned.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 4, 1887.

George F. Shrady, M.D., President, in the Chair.

Dr. Beverley Robinson read a paper (see p. 230) on

HEART-STRAIN AND WEAK HEART.

Dr. W. M. Carpenter was invited to open the discussion, and he remarked that he had never been able to entirely convince himself that the so-called "irritable heart" referred to by Dr. Robinson and described by DaCosta was a very frequent primary disorder. The relation between the centre of the circulatory apparatus and all other parts of the body was so intimate and constant that an exceedingly large percentage of functional disorders of the heart could be traced to external causes.

The carefully observed cases reported by Dr. Robinson, however, would lead to the conclusion that there is a certain percentage of cases in which what had been called irritable heart, or heart-strain, or weak heart, existed as a primary disorder. When, however, affections of the hepatic, gastro-intestinal, genito-urinary, pulmonary, and nervous systems were excluded, together with the affections belonging to the group of organic diseases of the heart, the number of cases could not be very large.

Dr. C. L. Dana had been very much interested in the paper, because attention had been directed to the possibility of the existence of muscular defect in some cases which are frequently, perhaps commonly, regarded as nervous disturbance of the heart, and the patients are told that they will get well. Still, it had been observed that in some of these cases digitalis had been taken with marked benefit. He was in some doubt, however, as to the extent to which we could speak of a weak heart, referring only to the muscular structure, and he was somewhat inclined to side with the view advanced by Dr. Carpenter. It seemed to him that the heart could not be regarded as a muscular organ alone, nor should its pathology be studied alone. For it is the end of certain sets of nerves, and in other parts of the body the pathology and physiology of the two go together, almost as much as do the fundus of the eye and the entire tract of the optic nerve.

Probably in most of the so-called cases of weak heart the trouble is nervous, and not muscular, and the therapeutics rather sustain that view. In addition, it has been found of late that there are actual changes in the cardiac nerves which produce symptoms resembling those said to belong to heart-strain. For example, in multiple neuritis there is almost always great dyspnœa and rapid heart action, with a pulse from ninety to one hundred without fever. In these cases also there is præcordial distress, and examination has revealed actual lesions of the pneumogastric nerve. Again, in cases of locomotor ataxy there are cardiac crises in which occur symptoms very similar to those said to be dependent on a weak heart without organic disease, and autopsy has revealed, here also, lesions of the pneumogastric nucleus and of the nerve. These cases show that diseases belonging to the nervous system are capable of producing lesions of the cardiac nerves.

Again, the author of the paper had reported one case which followed Chagres fever. It was well known that it was not rare for neuritis to follow such fevers, and it was not improbable that there were changes of that kind in the case cited.

At the last meeting of the Society he referred to the fact that Semmola had discovered changes in the cardiac nerves, and to the affection he had given the name "cardiac ataxia," occurring in persons who had been subject to severe strain for some time. Another confirmation was the fact that these cases occur very infrequently among laboring people, unless there are evidences of syphilis or arterial disease.

He would say, therefore, that severe physical labor alone does not cause heart weakness.

There was another interesting point to which he would refer, and it was that asynchronous beating of the heart was mentioned as one of the symptoms of heart-strain, or weak heart. Cases of that kind had been reported, but he had often wondered if any such thing did actually occur. It seemed to him it was extremely improbable that the ventricles should contract at unequal intervals. Experimentally, he did not recollect having seen the ventricles contract asynchronously.

Dr. J. B. Hunter had been impressed by the clinical fact that many persons suffered from cardiac symptoms without appreciable organic lesion, and he had also been impressed by the fact that these patients were, many of them, capable of performing a great amount of mental and physical labor. He recalled the case of a woman who died recently, who had suffered from marked cardiac disturbance during the last fifty years, but had conducted a large female seminary, and finally died of pneumonia.

He had had, in two cases, very marked cardiac symp-

toms in persons otherwise in perfect health, apparently. There was no evidence whatever of organic cardiac disease, and the cases had interested him very much with regard to the difficulty of making a prognosis. At all events, the condition of irritable heart, so called, according to his observation, was not incompatible with the performance of a large amount of work. At one time he hesitated with reference to administering ether to these patients, but had subsequently learned that they take anæsthetics without inconvenience, thus giving support to the probable explanation given by Dr. Dana, that there is a nervous lesion apart from the cardiac disorder.

Dr. Robinson, in closing the discussion, said that in the study of his cases he had very carefully eliminated the sources of error to which attention had been directed in the discussion, and, as a matter of fact, had been surprised to find that he had so many cases recorded which could not be explained by secondary causes.

With regard to the point made by Dr. Dana, he had no doubt that in many instances it was correct, and the correctness of the view was sustained by the cases cited by Dr. Hunter. At the same time, he believed that his paper would prove useful in directing attention to these peculiar cardiac cases, and enable us the better to separate and treat them.

The Society then adjourned.

NEW YORK PATHOLOGICAL SOCIETY.

Anniversary Meeting, January 12, 1887.

T. Mitchell Prudden, M.D., Vice-President, in the Chair.

REPORT OF THE COMMITTEE ON MICROSCOPY.

Dr. L. Waldstein reported that the specimen of *multiple abscess* of the lung with high temperature presented by Dr. Holt showed the changes belonging to acute rapidly progressing interstitial pneumonia, with degeneration and formation of abscesses. No tubercle bacilli were found.

Dr. G. C. Freeborn reported that the tumor removed from the roof of the mouth by Dr. Robert Newmann was a simple fibroma.

Dr. W. P. Northrup presented a lung removed from the body of a child three years of age that died of

PNEUMONIA FOLLOWING MEASLES.

The special feature of interest was the infiltration of the bronchi showing the bronchial tree. The pneumonia was mostly in the posterior portion of the lower lobe, slight in the upper lobe, and it was very acute.

Dr. W. H. Porter presented two lungs that illustrated

THE PECULIAR APPEARANCES OF PULMONARY SYPHILIS.

In the first case the patient entered the hospital in a semi-comatose condition, and died soon afterward. There were six or eight small nodules in the apex, and there were gummata in the pia-mata and the liver. He had been unable to find tubercle bacilli in the specimen, but had found the bacillus of Lüstgarten.

In the second case the man entered the Presbyterian Hospital suffering from acute pleurisy, from which he recovered. He died while undergoing an operation for hemorrhoids. One lung was found riddled with small cavities, while the other lung was unaffected.

With reference to microscopical examination of the lung-tissue in these cases, Dr. Porter had been unable to find Lüstgarten's bacillus except in the centre of the small nodules. He had never found it in either the bronchial secretion or in the cavities which had begun to discharge their contents.

Dr. Porter exhibited microscopic slides that showed the bacillus of syphilis.

Dr. L. Emmett Holt presented the lungs of a child eight months old that died of

PERSISTENT BRONCHO-PNEUMONIA.

The pneumonia was primary, and its only special feature was its duration. The amount of disease was considerable. The right upper lobe was completely solid, and seemed to be made up largely of connective tissue. At the extreme apex were four or five small abscesses. There was also infiltration of the bronchi and dilatation with cavities.

TYPHOID FEVER SIMULATING CEREBRO-SPINAL MENINGITIS.

Dr. R. W. Amidon presented specimens accompanied by remarks on the differential diagnosis between certain atypical cases of typhoid fever and cerebro-spinal meningitis.

The specimens were from the body of a woman, aged thirty, who was a patient of Dr. A. F. Currier. About November 19th she began to suffer from pain in temples and occiput, worse in the latter region, and much pain and stiffness in the back of the neck. She had some chills, and thought she had caught a severe cold. She was first seen by Dr. Currier November 26th, when all these symptoms were aggravated. Her temperature was 103.8° F., pulse 100, and she had *no* abdominal symptoms whatever. The nervous symptoms continued, and the temperature ran a peculiar course, there being a remission on the morning of December 6th. Some antifibrine was then being given, but not enough to explain the low temperature. Dr. Amidon saw the patient in consultation once only, December 8th, on the eighteenth day of the disease. Then, at 8 P.M., the temperature was 103.6° F., pulse, 90. The patient was not in a typhoid condition. She complained only of occiput headache, and pain and stiffness in the back of the neck, general sensitiveness, and twitching of the extremities. On examination, he found her to have marked photophobia, a very stiff neck, which was very sensitive to the touch, as was the occiput and spine, and there was marked general hyperæsthesia. There was no ileo-cæcal gurgling, nor was the abdomen more sensitive than the rest of the body. She had had no eruption, nor diarrhœa, the stools being normal, and assimilation of light food was apparently perfect. The absence of common symptoms of enteric fever, and especially the remission of the temperature, together with the marked prominence of nervous symptoms from the start, led Dr. Amidon to favor a diagnosis of cerebro-spinal meningitis. He gave a bad prognosis, and advised that a close watch be kept for an eruption, and also for enteric symptoms. December 8th, the temperature in the morning was 100.6° F., and at night the same.

December 10th.—With a rise of temperature came a rash which Dr. Currier said was bright and scarlatiniform, and covered *every part* of the body, and lasted several days.

December 21st.—The patient developed an acute bronchitis.

December 26th.—The temperature was normal, and remained so or subnormal *one week*.

January 1st.—She was overfed, and vomited. In the next few days the patient developed indubitable symptoms of septicæmia, with a very irregular temperature (higher in the morning) and frequent chills. These symptoms subsided, and on January 10th Dr. Currier considered the patient again convalescent.

January 11th.—She died suddenly of an immense intestinal hemorrhage in the eighth week of her illness. On autopsy the spleen was found to be about four times its usual size, dark and friable. The ileum and colon were nearly full of dark fluid blood. The ileum was the seat of many entirely healed Peyerian ulcers, and many unhealed ones, from one of which, about eighty centimetres from the valve, the fatal hemorrhage had occurred.

The cæcum and the ascending and transverse colon were the seat of small, round, elevated ulcers, many of them covered with grayish protruding sloughs, which evidently consisted of necrosed solitary follicles and the superjacent mucous membrane. The peritoneum covering the large ulcers in the ileum was covered by an organized fibrinous exudation having a punctate appearance.

Dr. Van Santvoord had, in two cases, met with septicæmia associated with symptoms that pointed toward cerebro-spinal meningitis. The first was a case of surgical kidney following an operation on a urethral stricture, and in the second the source of the septicæmia was an abscess of the hip-joint that had not opened externally.

Dr. L. Waldstein could scarcely recall a case, in all the post-mortem examinations he had witnessed in Europe, in which the intestinal lesions of typhoid fever were so marked in the colon as he had been accustomed to see them in New York during the last three or four years. During these three or four years he had hardly seen a post-mortem examination after typhoid which did not show that the colon was more or less involved; in many cases the lesions were almost entirely in the colon, and in the neighborhood of the ileo-cæcal valve in the ileum. He had often asked himself the question, Why this difference in appearance? and he would ask those who had had more experience in the treatment of the disease than he had if the use of drugs here which were not used in typhoid fever abroad might not be the cause. He had thought it possible that this colo-typhoid might be auto-infectious, and thus the poison be carried into the colon. Perhaps the antiseptic method of treatment employed extensively abroad might explain the rarity of the lesions in the colon—that is, the calomel treatment in the incipiency of the disease.

Dr. J. C. Peters said that he saw typhoid fever with Schoenlein in Berlin, and attended post-mortem examinations with Rokitansky, where he saw the typical morbid appearances of the intestines, in which the ileum was largely involved and the colon but little or none at all. In the early history of typhoid fever, in New York, the same appearances were seen, and it was only quite recently that the involvement of the large intestine had been observed.

Dr. Amidon said Dr. Peabody had mentioned to him that he had never seen a case in which the existence of cerebro-spinal meningitis was suspected and the autopsy revealed typhoid fever, but that he had made a post-mortem in a case in which typhoid fever was diagnosticated, and it was found that the patient died of cerebro-spinal meningitis.

Dr. Wesley M. Carpenter spoke of a group of cases of typhoid fever which he saw several years ago, and in which cerebro-spinal symptoms predominated; in some cases throughout, but in most for ten or twelve days at the outset, and from that time on the symptoms were those of typhoid fever as ordinarily seen. The most marked case was that of a woman whose symptoms were so obscure, but so markedly cerebral, that the diagnosis was "an obscure manifestation of some inflammatory disease of the brain or its membranes." The case terminated fatally. A neighbor's wife, who was with and waited upon the patient a considerable part of the time, especially at night, was taken sick with unmistakable typhoid fever, and died of hemorrhage of the bowels. All the other patients recovered. The severity of the cerebro-spinal symptoms was greatest at the beginning of the season of the appearance of the fever, and diminished as the season advanced.

The Society then went into executive session.

The college clinics are prosperous, the hospitals are full, clinical material is abundant, and the young practitioner waits in vain for patients.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

MR. SUTTON'S RESEARCHES IN COMPARATIVE PATHOLOGY —TUBERCULAR DISEASE OF THE SKULL—TWO CASES OF RECOVERY FROM RUPTURE OF THE BLADDER—A CASE OF SCURVY.

London, February 5, 1887.

At the Pathological Society, on Tuesday last, Mr. J. B Sutton read a paper embodying an account of some further researches which he had made in comparative pathology. Mr. Sutton has now been working for some years in this field. In the present paper he dealt with diseases of the genito-urinary organs in animals. A specimen was shown of the kidney of a sloth with two calculi of oxalate of lime in its pelvis. The animal had lived in the Zoological Gardens for twelve years. Mr. Sutton remarked that renal calculi were excessively rare in wild animals, but not uncommon in domesticated ones. A case of distension of the vaginal, cervical, and uterine cavities of a hog-deer was described. A uterus from an agouti was shown in which some pieces of placenta and fœtal membranes had been retained; suppurative endometritis had ensued, and an ovarian abscess had formed and caused a fatal attack of peritonitis by bursting into the peritoneum. Another interesting specimen shown was that of the uterus of a baboon with the viscera *in situ*, the uterus being in a state of acute retroflexion. In reply to a question from Sir James Paget, Mr. Sutton said the first year at the Zoological Gardens settled the question whether an animal would become diseased or whether it would become acclimatized.

A specimen which evoked considerable interest was one shown by Mr. Bilton Pollard. It was taken from a female child who had died at the age of sixteen months, and consisted of the vault of the skull. In this were four perforations which Mr. Pollard believed to be due to tubercular disease of the bone. The child was first seen when ten months old. There were then four chronic abscesses on the skull. These were scraped out. The smallest one healed, but the others remained fistulous. A fifth one formed and ran a similar course. Four months later, sequestræ, involving the whole thickness of the skull, were removed. Three of the abscesses then healed, but the child wasted and died in two months. Patches of caseous tubercle were found in the lungs and the bronchial glands were caseous. The skull showed four perforations, but in three of these the borders were smooth and healthy. Along the upper border of the other perforation (one in the occipital bone) there were still signs of disease present. Mr. Pollard said he had examined some of the granulation tissue and one of the pieces of bone which had come away. They showed the structure of tubercle on microscopical examination, but he had failed to find any bacilli. There were no signs of syphilis in the skull. Volkmann had described similar cases of tubercular disease of the skull causing perforation. Mr. Barling remarked that he had seen a similar specimen in a child. Several speakers made remarks on the subject, and the rarity of the specimen was recognized generally. Mr. Pollard, in replying, remarked that Volkmann had collected eleven cases of tubercular disease of the skull. In some of these, caries, rather than necrosis, was the chief feature. In his own specimen, the diseased bone appears to have been previously infiltrated with tubercular material and then periostitis, ending in necrosis, had occurred.

Sir William MacCormac has lately had under his care at St. Thomas' Hospital two cases of rupture of the bladder ending in recovery. Curiously enough, the cases occurred within a month of each other, the patients being admitted on successive taking-in days. In neither were

the symptoms at first very well marked. In one they were so slight that the house-surgeon, who first saw the patient, sent him home, and he only returned to the hospital on the symptoms becoming aggravated. The other patient walked to the hospital immediately after the accident—a distance of about a mile. In both cases Sir William MacCormac performed a very similar operation. The abdomen was opened, the rent in the bladder closed by sutures, and the abdominal wound then closed. The opening in the bladder was about four inches in length in one case—two inches in the other. Both the patients were males. Antiseptic precautions were employed throughout, and the cavity freely irrigated with antiseptic solution, before closing the abdominal wound. Both patients recovered without the occurrence of a single bad symptom or any noteworthy rise of temperature. The cases are shortly to be brought before one of the London societies. No case of intra-peritoneal rupture of the bladder has, I believe, previously been placed on record in this country. In Mr. Rivington's monograph on the subject he refers to eight reported cases of recovery after intra-peritoneal rupture. Seven of these, however, he thinks not sufficiently established. The solitary exception is a case recorded by Dr. Walter in the Philadelphia *Medical and Surgical Reporter* for 1862.

A seaman has recently died at Greenwich from scurvy. He embarked at Calcutta for England in August last, and became affected with scurvy on the voyage, the dietary on board ship not being sufficiently varied. He was taken to the Seamen's Hospital at Greenwich on landing, but expired from syncope on reaching the hospital. Another seaman was also affected, but less severely, and he recovered.

"REPORT OF A CASE OF TYPHOID FEVER IN WHICH ANTIFEBRIN WAS USED SUCCESSFULLY AS AN ANTIPYRETIC AGENT."

To the Editor of The Medical Record.

Sir: The Medical Record of January 29, 1887, contains a letter from Dr. N. E. Jones regarding my article published in that journal of January 1, 1887, bearing the above title. The doctor's plea for the use of your columns is a desire to find out more about the treatment of typhoid fever in New York. He at once, however, launches into the field of bold and undignified assertions, implying that the death of the patient was due to the drug employed. Everything in the way of *bona fide* criticism, which is always desirable and to which no one can reasonably object, is wanting in your correspondent's communication. His reasoning is *post hoc ergo propter hoc.*

The careful observations made and recorded, such as noting the exact influence of the remedy upon the heart, respiration, and temperature after the administration of each dose, the cautious methods adopted in using the minimum quantity to get a certain effect, stopping the administration of the drug at the first indication that there was a tendency to a natural morning remission of the temperature, the death of the patient from *intestinal perforation five days after the remedy had been discontinued*—all these your correspondent passes unnoticed, unmet by any attempt at rational criticism. He will doubtless not deny that typhoid patients may die from intestinal perforation who have not taken antifebrin.

In taking exception to our attempt to control a temperature which was continuous without a morning remission, the doctor asks, "Does anyone know that it is the temperature that destroys the patient? In early days it was not considered true science to prescribe for some prominent symptom, and give no attention to the pathological condition of the suffering organs."

Our close attention to the pathological condition of the suffering organs was the reason for our attempt to control the temperature. Let your correspondent recall the state of the vital organs in two patients who have died from typhoid fever—one where high temperature had predominated, the other where high temperature had not been a prominent symptom. If such an opportunity has not presented itself, let him seize the first, and note the flabby character of the heart, liver, and kidneys of the one and the comparative firmness of these organs in the other. Let him go further, and make section of these organs in their recent state, and carry them to his microscope and note the differences in the parenchyma which open to his view.

This is no time or place to discuss the value of antipyretic agents. Carefully made statistics would seem to leave their value unquestioned. Liebermeister, Gutman, Ebstein, Griesinger, Leibnitz, all who have had excellent opportunities to judge, voice their sentiments, backed by well-collected statistics, in no doubtful tone regarding the efficacy of antipyretic measures.

I pass the query, "Does anyone suppose a rise of the temperature-point necessarily implies an increase of the production of heat?"

The imputation that a desire to advertise a new remedy prompted the article is false. Conservatism in the employment of new drugs and innovations in medicine is wise, but were all as conservative as your correspondent would appear, there would be no progress, and we would still be struggling with the superstition and ignorance of the middle ages. The intention is not to argue for the reckless employment of new remedies; such was not the spirit which prompted the use of antifebrin. The condition of our patient seemed to demand a certain kind of treatment. Antipyrin was rejected because it had not acted well in our hands, and antifebrin was offered to the profession backed by an excellent showing of results. The effect, in our judgment, was more than satisfactory. In the same number of The Medical Record which contains your correspondent's letter, Dr. J. L. R. Wadsworth reports employing it successfully in the treatment of his daughter when the condition of the patient was most unfavorable for any depressant. I have since employed the drug, and thus far have had only good results. Dr. Fordyce Barker tells me he has employed it frequently in four-grain doses with the most flattering effect, and has yet to meet with a bad result. Dr. E. G. Janeway tells me he has employed it in a great many cases in both hospital and private practice, and considers it the safest, most reliable, and certain antipyretic agent we have. No bad results have followed its employment in his hands.

If we are to confine ourselves to the use simply of old drugs and old formulas then is the practice of medicine indeed reduced to empiricism, and progress fatally handicapped. A physician should be able to employ any drug, having in view a distinct idea of why he employs it, and know how to interpret the result. A mariner heads his ship into an undiscovered region, but, if he makes careful observations and is competent to utilize such observations, voyages in safety. The surgeon's knife in skilled hands oftentimes safely explores uncertain regions, and as often surmounts difficulties which could not possibly be foreseen. Strong agents like aconite, strychnine, gelsemium, etc., are only satisfactorily employed when careful observation of the effect is made the basis for their use.

To blindly give a drug from an empirical stand-point is often as unwise as it is unscientific, but caution accompanied by an intelligent interpretation of the effect we are getting should enable us to use the most deadly agent with safety. In this way we tried to employ antifebrin, and published our chart. A review of the latter by your correspondent will convince him, I think, that he has misinterpreted our reckonings and misjudged our calculations.

George R. Elliott, M.D.

A doctor's bowling club has been organized in this city. The members are as skilful with the balls as with the boluses, and many a ten-strike results.

THE DANGER FROM ETHER IN NEPHRITIS.

SUUM CUIQUE TRIBUERE.

To the Editor of The Medical Record.

Sir: If only for the sake of adding to the value of my paper, I should have mentioned in my article on "The Dangers of the Administration of Ether in Nephritis and Bright's Disease," published in your issue of January 29th, the valuable and original contributions to medical science by Dr. Thomas Addis Emmett upon this subject, as well as an important paper by Dr. R. Van Santvoord, published in The Medical Record of March 10, 1883. The paper, by Dr. Wesley M. Carpenter, referred to by me, contains extracts from Dr. Emmett's work of great weight relative to this important matter, and though I have not until to-day read in his book what he has there written, his experiences and opinions as I have met with them from time to time in medical journals are well known to me. I believe it incumbent upon me to add as a supplement to my paper that Dr. Emmett was the first one, so far as I can ascertain, to call the attention of the medical profession to a danger now generally recognized, and that we are all greatly indebted to him for this, as well as to his moral courage in publishing the accounts of the cases which terminated so disastrously.

Henry B. Millard, M.D.

February 14, 1887.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 13 to February 19, 1887.

Smith, Joseph R., Lieutenant-Colonel and Surgeon. Detailed, in addition to his present duties, as President of the Army Medical Board in New York City, N. Y. S. O. 38, A. G. O., February 15, 1887.

Tremaine, W. S., Major and Surgeon. Sick leave still further extended four months, on surgeon's certificate of disability. S. O. 39, A. G. O., February 16, 1887.

McCreery, George, Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 35, A. G. O., February 11, 1887.

Taylor, Arthur W., Captain and Assistant Surgeon. Relieved from duty at Camp Medicine, Butte, Wyo. Ter., and ordered for duty at Fort Laramie, Wyo. Ter. S. O. 14, Department of the Platte, February 12, 1887.

Wyeth, M. C., Captain and Assistant Surgeon. Ordered from Fort Wayne, Mich., to Fort Barrancas, Fla. S. O. 39, A. G. O., February 16, 1887.

Morris, Edward R., First Lieutenant and Assistant Surgeon. Leave of absence extended twenty days. S. O. 35, A. G. O., February 11, 1887.

Wakeman, William J., First Lieutenant and Assistant Surgeon. Relieved from duty in Department of the Platte, to take effect on the expiration of his present leave of absence, and ordered for duty at Fort Walla Walla, Wash. Ter. S. O. 36, A. G. O., February 12, 1887.

The Abuse of Medical Charity.—It is stated that a few days since a woman dressed in rags applied at the Boston City Hospital for surgical treatment for a scalp wound. The customary search of her person revealed several bank-books, representing $7,100 in Boston banks, $1,000 in bonds, and about $300 in cash—all hidden about her clothing.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 19, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	3
Scarlet fever	47	7
Cerebro-spinal meningitis	3	2
Measles	364	53
Diphtheria	75	37
Small-pox	13	6
Yellow fever	0	0

The Data of the Chin.—The dignified and old-school Medical Record reproves a "thoughtful contemporary for attempting to establish a philosophic relation between the 'art of medicine' and the fact that a large proportion of the American Medical Association are bald-headed men." It thinks the doctor's beard is "a much more practical problem," is pained to notice that American physicians have a tendency to long beards which, duty prompts it to say, "ought to go"—to go on sanitary and æsthetic grounds, and because long beards are a "characteristic of an undeveloped civilization." All this is severe on the long-bearded M.D.'s, but there is worse a-coming. Hearken to this! "Hardly a doctor of the first eminence in the world's history ever wore a long beard, and he who possesses one may as well concede at once that he will never rise above mediocrity." All the great doctors of old "patronized the barber, and turned the physiological energies that might have been lost in making hair into making brains." What a confusedly crushing and conflicting crowd of ideas these *ex cathedra* enunciations hurl down on the hapless reader! The hygienic question goes glimmering before the great discovery that hair-energy and brain-energy are one. Granting this, it is indisputably true that the doctor who lets his energy go to his chin does so at the expense of his brain. Mark well, ye doctors! subdue your chin-energy, that you may rise above mediocrity! patronize the barber if you aspire to be a shining light! But soft! what lurking heresy is here? The barber cures your chin-energy, and the barber, from far times, has been noted for—chin-energy; *similia similibus curantur*. Interesting as the question is, we cannot pause to discuss whether the closely shaved doctor could be called "hair-brained" or not—probably not, as Shakespeare spells it, "hare-brained." Neither can we now consider that great physiological question that our esteemed contemporary has so suddenly sprung. If not hair, what, then, is that energetic crop that so persistently sprouts on the chin of the doctor who "patronizes the barber" and thereby soars into dazzling professional eminence, *via* the barber-chair? Alas, how The Medical Record has hurled headlong into ruin all the old and accepted data of the chin.—*Hom. Recorder*.

The Central Texas Medical Association held its second quarterly meeting at Waco, Tex., on January 12th. Several new members were elected, an interesting address was delivered by the President, Dr. F. M. Pitts, and a paper on "Typho-malarial Fever," so called, was read by Dr. H. W. Dudley.

Hysterical Speroma Cured by Circumcision.—A correspondent writing from Canada, under the title of "Only a General Practitioner" says: "A young gentleman, aged twenty-one, called on me a few days ago. He prefaced his visit by asking me in a hoarse whisper: 'Are you a general doctor?' Supposing him to mean a general practitioner, I answered in the affirmative. He then stated in the same whisper that he was a victim of

self-abuse, and thought, as such poor devils nearly all think when they get frightened, that he was ruined for life *quoad* virility. I asked him concerning his general health, which he said was perfect, with the exception of this hoarseness. For this, he said, he wished no treatment at my hands, as he was now being treated and had been treated by a specialist for the past few months. The specialist's diagnosis was 'paralysis of vocal cords,' requiring months of further treatment to cure. The treatment was local. Out of curiosity I took him into my dark room and carefully examined his larynx, but could find nothing to confirm our local specialist's diagnosis. As said specialist is also a general practitioner, and specializes eyes, ears, wombs, etc., as well, I may have had my own suspicions from the first—but of this no more. I expressed no opinion to the patient. I then examined his genitalia, and found a long, tight prepuce, with moist, sodden glans, and advised him as a preliminary step to have it removed. He agreed, and next morning I operated. I used ten per cent. solution of cocaine, injecting a few drops in the line of excision. I did this so that he should have the moral benefit of the operation. It was a complete success—so much so, indeed, that I made a mental note in any future operation of a similar character to use cocaine instead of a general anæsthetic. This was my first experience with the drug, except in ligating hæmorrhoid, outside of its ophthalmic use. On visiting my patient a few hours after, I was surprised to find that he had had a copious hemorrhage, which was still in progress, though the wound was quite dry when I had dressed it. But what was more surprising, my patient's vocal paralysis was quite gone, and he spoke as strongly and well as ever. Up to date he has full control of his throat, and sings a very fine tenor. Perhaps you will accept this addenda to our therapeutics and consider it a new remedy for paralysis of the recurrent laryngeal, or you may suggest that throat and genito-urinary specialists should make a combination sometimes."

The Mortality from Childbirth diminishes every year, especially in lying-in hospitals. In the Maternity Hospital at Liége there were delivered, in 1886, 417 cases without a death and with hardly a rise of temperature. Dr. Charles, the director, thinks the result due to the faithful use of corrosive sublimate.

Tinctura Ferri Citro-chloridi (Tincture of Citro-chloride of Iron—Tasteless Tincture of Iron).—

℞. Sol. chloride of iron (U. S. Ph.)..	f ℥	4
Citric acid.....	gr.	2,100
Bicarbonate of sodium.....	gr.	2,270
Alcohol	f ℥	4
Water .....q. s. ad	f ℥	16

Dissolve the citric acid in 4 fluid ounces of water, heat the solution to the boiling-point, and gradually add the bicarbonate of sodium. When effervescence has ceased, add the solution of chloride of iron, and cool the mixture. Then add enough water to make it measure 12 fluid ounces, and finally add the alcohol. Each fluid drachm contains about 7½ grains of dry ferric chloride. Note: This tincture is approximately of the same strength, in metallic iron, as the official tinctura ferri chloridi.—*National Druggist*, September 10, 1886.

Cocaine in Circumcision.—Dr. Kingsley, of San Antonio, Tex., writes that in his communication, appearing in these columns under date of November 13, 1886, he did not intend to claim absolute priority in the use of cocaine in circumcision, but only meant to claim that he had performed the operation nearly a year before Dr. Palmer. His object was more especially to illustrate the complete success of the operation in removing a series of distressing symptoms, more the result of a disordered imagination than of any visible pathological condition. Dr. M. E. Alderson, of Russellville, Ky., states that he performed circumcision under cocaine on January 23, 1885, having used the same anæsthetic in an operation for hæmorrhoids on January 5th of the same year. A short time after this he removed the entire second finger of one hand for a gun-shot injury by which the second metacarpal bone was shattered. One-half grain of cocaine was injected on each side of the metacarpo-phalangeal articulation, and the operation was performed satisfactorily, no other anæsthetic being used.

Reflex Symptoms and their Significance.—The *Pacific Record* gives the following symptoms, with their pathological interpretation. Some of these interpretations, however, must be taken with considerable reservation: Swelling under the eyes, grayish, white, or waxy color of the skin, denotes granular (?) disease of kidney. Swelling of the labia, on one or both sides, will accompany inflammation of kidney. Carbuncles on the shoulders, or scapular region (and forearm), are frequently accompaniments of diabetes. Pain, referred to the meatus urinarius, is sure to be the result of cystitis, prostatitis, or nephritis (?). Pruritus of the anus will be the evidence, sometimes, of disease of the prostate. Pain or numbness in the outer part of the thigh denotes some disturbance of the sexual organs, in both male and female. Sciatic neuralgia often (?) depends, in females, on inflammation of the ovary; in men, irritation of lumbar or sacral nerves. Pain in the heels (in females) may be the only evidence of ovarian abscess, while pain and swelling in the mammæ will evince some trouble in the same side of uterus, or Fallopian tube. That shortness of breath, or asthmatic breathing, may indicate valvular disease, or aneurism of the aorta, is probably as well known as that discoloration of the skin may be due to cirrhosis of the liver, or to disease of the suprarenal capsule. Sharp outlines of the facial muscles, a peculiar, querulous look, surely define a dyspeptic, and are not to be mistaken even as the expression of a temporary pain. A dull, aching pain in the *right* shoulder will arise from congestion of the *right* lobe of the liver, while disturbance in the *left* lobe (?), as well as *gastric ulcer*, will give ache, or pain, in the left. Some heart diseases, notably dilatation of the left ventricle, will give pain in the coracoid process, radiating into the left arm; but this pain will stop at a point half-way to the elbow. *Swollen feet* should warn us of some organic disease of heart, kidney, or liver. Hot feet and hands accompany dyspepsia, while a *red nose* will be an indication of *gastric irritation*, either from indigestion or whiskey. But the appearance of the hands is by far the best evidence we possess for instantaneous diagnosis. Not always to be depended on, it is true, as an entity, but, corroborated by other symptoms, will hardly fail. Dr. Watson first noticed a club-shaped form of the ends of the second and third digits as pathognomic of tuberculosis. Finger-nails, white at the points and purple at the base, *always* accompany the chills of malarial fever. A white appearance of the fingers in contrast with the back of the hand, will denote a very torpid condition of the bowels. A yellow tinge in the palm or under the finger-nails, produced by pressure, will indicate torpidity of liver.

Nervous Depression and the Development of Cancer.—Dr. George H. Rohé, in the Philadelphia *Medical Times*, writes: "It looks very improbable at first sight that new-growths, especially cancer, should be rationably attributable to the influence of nervous depression. However, so acute an observer as Sir James Paget seems to incline to the view that such a relation may possibly exist. Snow states that of one hundred and forty cases of mammary cancer analyzed by him, 'one hundred and three gave an account of previous mental trouble, hard work, or other debilitating agency.' Of one hundred and eighty-seven cases of uterine cancer, nearly one-half (ninety-one) gave a similar history. A number of detailed histories given by this author seem

to bear out the claim that mental depression (neurasthenia) is a frequent cause of cancer. Arndt is positive that neurasthenia is an etiological forerunner of cancer, and relates three illustrative cases. Willard Parker states that 'there are the strongest physiological reasons for believing that great mental depression, particularly grief, induces a predisposition to such a disease as cancer, or becomes an exciting cause under circumstances where the disease had already been acquired.' In over one-fourth of Parker's cases of cancer of the breast (one hundred and six out of three hundred and ninety-seven), nervous depression or conditions directly leading to it are set down as forerunners of the disease. Cooke points out the fact that in women cancer occurs, on an average, ten years earlier than in men, coinciding in the former sex with the menopause, and in the latter with the period of greatest exhaustion of the nervous system. He remarks that 'the women of fifty are very generally more worn and wasted than the men of seventy.' It is between the fiftieth and sixtieth years that neurasthenia from professional overwork is most frequent. The merchant, official, or professional man is reminded that he cannot do the same amount of work at fifty that he could at thirty; in the words of a distinguished Philadelphia teacher of the last generation, 'he cannot get a three-minute pace out of a four-minute horse.' Jonathan Hutchinson says, upon the same point: 'We shall probably be not far from the truth if we admit senility of tissues, local or general, to be the one predisposing cause of cancer with which we are acquainted. . . . A little step further may next be taken, in the belief that everything which hastens senility, either local or general, will increase the predisposing influence, and in this category may be placed anxiety, distress, overwork, and excesses of all kinds. It is highly probable that under such conditions a state involving increased proneness to cancer may be induced, and, further, that if offspring are produced after that state has been developed, they will inherit that tendency.'"

The Indian and Physical Pain.—The general idea that the Indian endures pain stoically is not sustained by the observations of Dr. Corbusier among the Apaches. He says that "they do not endure physical pain any better, if as well, as the whites. Great or continuous pain renders them stupid, and oftentimes delirious, and the stolidity with which Indians in general are credited is not well maintained by them under small surgical operations, the one of tooth-extracting almost always eliciting a groan or a yell. The expression of their faces cannot always be seen on account of paint and their long hair, but when not concealed by these, the changes induced by the emotions may readily be detected; anger is almost always betrayed by the expression of the eyes; fear by the dirty grayish color the skin assumes; surprise by suddenly drawing in a breath as if gasping, and sometimes also by covering the mouth with one hand."

Thinking and Working.—In our present system of education—now happily passing away for a better one—we want one man to be always thinking and another to be always working; and we call the one a gentleman and the other an operative; whereas the workman ought often to be thinking and the thinker often to be working, and both should be gentlemen in the best sense. As it is, we make both ungentle, the one envying, the other despising, the other; and the mass of society is made up of morbid unhealthy thinkers and miserable workers. It is only by labor that thought can be made happy; and the professions should be liberal, and there should be less pride felt in peculiarity of employment, and more in the excellence of achievement.—*The Popular Science News.*

The Rattlesnake Treatment for the Relief of Pain.—Dr. William H. Corbusier, in an article on "The Apache-Yumans and Apache-Mojaves" (*American Antiquarian*), says: "The Apache-Mojaves sometimes resort to the Tonto medicine-men to receive the rattlesnake treatment for the relief of pain. At the Agency, one day, the rattling of a snake attracted my attention, and on approaching a group of Indians from which the sound seemed to proceed, I found a medicine-man squatting down holding a large rattlesnake in his right hand, the thumb and index finger of which encircled it close to its head, while he gently stroked its back with his left. Presently an old man advanced to him, and, saying he had a pain in his head, squatted on the ground. The medicine-man arose, and, placing himself behind his patient, coiled the snake around his head, and, while holding it there, uttered a guttural chant, occasionally causing the snake to vibrate its rattles. He then quickly uncoiled the snake and swung it head foremost away from the man's head, at the same time making the sound *wisht*. The man then pointed to his right arm, and the medicine-man laid the snake along the limb, its head resting on the hand. He chanted again, caused it to rattle, and swung it away as before. The old man arose, and with a satisfied air walked away. Other patients succeeded him, to have the snake laid on various parts of the body. After a time the medicine-man rested the snake on the ground again, and, still retaining his hold of it with his right hand, put a pinch of yellow pollen into its mouth with his left, and rubbed some along its belly. He then held his hand out to a man, who took a pinch of the powder and rubbed it on the crown of a boy's head. Yellow pollen treated in this manner is a common remedy for headache, and may frequently be seen on the crown of the head of men and boys."

Ulcers of Stomach in Infantile Tuberculosis.—At a recent meeting of the London Pathological Society, Dr. Barlow showed a specimen of tubercular ulcer in the stomach of a child twenty-one months old, affected with general tuberculosis. It was situate near the cardiac end in the great curvature; had undermined edges, but no thickening around. There were also follicular ulcers at the mid-point of the great curvature, and two near the pylorus. In the first ulcer there was a minute elevation under the mucous membrane, which might have been a miliary tubercle, but had not yet been searched for bacilli. The interest of the case lay in the relation of the small tubercle to the ulcer. Small ulcers of the stomach had been found in adult phthisis. Louis said he had never once seen anything like tubercle in these, and Andral had only once found tubercle of the stomach. Of 146 cases of tuberculosis in children, Barthez and Rilliet found 21 with the stomach affected, and in 7 of these there were miliary tubercles. They had no doubt that the ulcers were caused by tubercle. He had seen two other cases of this kind, but not with miliary tubercle in their base.—*The Lancet*, January 1, 1887.

Mortality in Childbed in Public Institutions in Germany from 1874 to 1883.—Dr. R. Dohm has collected statistics of 104,287 cases of labor in the public institutions in Germany during the ten years named (*Medical Press*). The mortality was 1.37 per cent., or not one-half of what obtained in the pre-antiseptic age, when it was reckoned at 3.4 per cent. The tables also show that the lowest mortality is in the lying-in hospitals in which no teaching work is carried on (0.56 per cent.). The middle grade of mortality is in hospitals in which midwives are trained (1.13 per cent.), while the mortality of institutions to which students are admitted is 1.90 per cent. As is pointed out by the author, however, this may be accounted for by the fact that pathological cases are attracted to these institutions. The truth of this would seem to be borne out by the statistics of the Royal University Women's Klinik, Berlin, tabulated by W. Bokelmann. In that hospital puerperal eclampsia occurred once in every 49 cases (average 1 in 500), placenta prævia 1 in 88 (average 1 in 400 to 500), rupture of the uterus 1 in 195 (against 1 in 527 and 1,722 in Tübingen and Munich, and 1 in 5,664 in the Berlin Charité).

ON THE CURE OF REDUCIBLE AND IRREDUCIBLE HERNIAS BY HEATON'S INJECTION METHOD AND BY RADICAL OPERATION.[1]

BY ROBERT F. WEIR, M.D.,

PROFESSOR OF CLINICAL SURGERY, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; SURGEON TO THE NEW YORK HOSPITAL.

Two years before the publication by Dr. George Heaton of his little book on the cure of rupture, etc.,[2] in 1877, I had seen two patients who had been cured by him, by a then unknown method of subcutaneous injection. The satisfactory result was confirmed by the inspection of the parts formerly the site of the hernias. I was consequently easily led, on the announcement of this long-concealed method, to test its efficacy, and soon had an experience sufficiently large to come to the conclusion that it was, as asserted, a reliable procedure, but to a much more limited degree than its introducer and his immediate disciples claimed.

This procedure consists, as is well known, in injecting, by a syringe with a larger and longer point than in an ordinary hypodermic syringe, into the cellular tissue of the inguinal canal, and after the reduction of the hernia, some ten to twenty minims of a mixture of half an ounce of Thayer's fluid extract of white-oak bark, thickened properly with the addition of fourteen grains of the solid extract of the same bark; to this was also put half a grain of morphine to allay the pain sometimes created. This mixture—or its modification by Warren of adding to ℥ ss. of Heaton's oak-bark mixture, evaporated to the thickness of glycerine, ℥ j. absolute alcohol, and ℥ j. sulphuric ether, and 2 grains of sulphate of morphia—was intended to effect a mild inflammatory thickening of the part to which it was applied, with a subsequent organization of new connective tissue, and thus to block up the hernial passage.

In carrying the injection into the inguinal canal, it was directed by Heaton that the left forefinger should be pressed perpendicularly into the external ring, in such a way as to crowd the spermatic cord to the inside, and thus to feel distinctly the external edge of the opening. The needle of the syringe is then to be forced through the ring and obliquely upward into the canal toward the region of the internal ring, and as it is withdrawn the mixture is to be injected, and at the same time the point of the needle moved in various directions, so as to smear with the fluid as large an area as possible. Arrived again at the external ring, the needle should be withdrawn suddenly, in order to prevent the injection affecting the subcutaneous tissue. A firm compress is then to be applied and the patient kept in bed for a week or ten days, depending on the amount of tenderness produced. At the end of this time the patient is generally able to go about, guarded for two or three months by a compress and bandage or by a light truss. Tests by coughing, etc., should not be resorted to until considerable time has elapsed. A conical compress made of multiple layers of rubber adhesive plaster can be more easily kept in place than an ordinary muslin one. Should the hernia reappear, a second, third, or fourth injection may be made.

In the first twenty-eight cases[1] in which I performed this operation, the results were uncertain and unsatisfactory; in these I had but eight cures, and a majority of these required more than one injection. Although it seems like an easy procedure, yet I found at first considerable difficulty in successfully planting my injection in the canal. Plunging the needle perpendicularly into the external ring sometimes led to its point being caught in and penetrating the external pillar, or even to its sliding out of the ring into the adjoining cellular tissue, or to its impinging at times on the cord, thus producing great pain, and occasionally epididymitis. To avoid these contretemps I first tried to thrust the needle into the external ring alongside the finger, after having invaginated the scrotum, from below; which manœuvre I found apt to be followed by a long indurated cord; and even when successful the canal was invaded only to a very limited extent, from the needle being too short for such a procedure. Even when experience had led me to the method of operating which I now use, the natural fear that I should, by pushing the needle in too far, inject the fluid into the peritoneal cavity, deterred me for some time in carrying the injection to the deeper part of the inguinal canal. In only one of my seventy-two cases did, however, this accident happen, and it did no harm, and, in fact, was not recognized until the death of the patient, four months later, from another disease, revealed that the injection had been carried into a mass of omentum which had not been completely reduced.

FIG. 1.—Heaton's Syringe, modified.

Nowadays, after altering the syringe devised by Heaton[2] so that its needle part is longer and stouter (as is here seen), and also adding to it a collar of roughened metal about its middle (see Fig. 1), I have used it in inguinal hernia in the following way: The patient is placed on a table with the hips slightly elevated; the hernia is reduced (though probably the sac cannot often be pushed up) and the ring identified as has already been described. Then the needle is carried through the skin alongside the end of the finger with a rotatory motion, avoiding in this manner anything like a thrust, until the ring is reached, or thought to be reached. The finger which had marked the external ring is now used to invaginate the scrotum and to recognize the situation of the needle-point, and to guide it as it is depressed and pushed upward and outward by the other hand. If not already determined by a preliminary examination, the length of the canal can often be estimated before the final discharge of the fluid takes place. I have many times been able to appreciate that the needle has gone through the intercolumnar fascia by a perceptible jump or jar, and this is of moment, for this fascia can be sometimes pushed upward to quite an extent, and if the fluid be then forced out it will, on the taking away of the needle, be found to be entirely external to the ring.[3] Mastering these de-

[2] The Cure of Rupture Reducible and Irreducible; also of Varicocele and Hydrocele, by New Methods. By George Heaton, M.D. Edited by Dr. Henry Davenport. 1877.

[1] Reported in THE MEDICAL RECORD of November 11, 1882, p. 551.

[2] At one time I employed De Garmo's guarded needle, but have been more pleased with the modified Heaton needle, as described in the text.

[3] Dr. Abbe has lately, with advantage, pushed the needle into the canal by purposely puncturing above the ring, guiding it by a finger of the other hand invaginating the scrotum.

tails, the operation became an easy one. But moderate pain is occasioned, and suppuration has in none of my cases occurred, and in but three or four adult cases was an anæsthetic required. If successfully applied, at the end of a week a hard plug, the size and shape of the end of the finger, can be felt through the abdominal walls or by invaginating the scrotum. This mass I have had the opportunity of inspecting in two hernias submitted subsequently to the radical operation, in one case three weeks, and in a second case eight months, after Heaton's injection had been practised. They formed brown masses of firm connective tissue, easily recognizable, and amply sufficient in size, had they been rightly placed, to block up the canal of a small hernia.

The outcome of my personal experience with this method can be summed up in a few words. The most satisfactory results have been had in inguinal hernias of small size and of tolerably short duration, that is to say, in those having an inguinal canal yet oblique. In larger and older hernias the use of a single or repeated injection will often so narrow the canal as to permit the easier use of a truss, and so allow of the better carrying on of a vocation. Moreover, the procedure is a perfectly safe one. Figures will, perhaps, be serviceable in appreciating these conclusions.

I have myself performed this operation altogether seventy-two times; those in private practice being in selected cases, but in hospital practice often in large hernias occurring in patients refusing the radical cutting operation. Of the 72 cases, all but 8 were for inguinal hernias. Of these 8, 3 were femoral hernias, with one cure; 2 umbilical, both failures; and 3 ventral ruptures, all cured by a single injection. Of the 64 inguinal hernias thus treated there have been 35 cases whose progress has been traced beyond eight months from the time of the operation, and of these there are 12 cases of cure; and in 8 of them it is further known that they are yet well in varying periods from two to five years. This would give a success of a little over thirty-three per cent. This is a somewhat better result than is given in the reliable reports of Bull [1] and Gay.[2] These observers give a total of 36 cases, with 9 cures, or twenty-five per cent. of recoveries. This discrepancy is explicable by the circumstance that not only have the more recent trials been largely restricted to the smaller hernias, but especially has success been achieved by me in four instances in children under ten years of age, in whom the long use of a truss had failed to relieve the hernia. A single injection under ether in each instance effectually controlled the hernial descent. Adding to my own figures, therefore, those of the above observers, 71 cases are obtained, with 21 cures, or a percentage of 29.5.

These statistics give a less encouraging outlook for this simple procedure than is furnished in a recent paper on this subject by Dr. W. B. De Garmo,[3] who states somewhat vaguely that the success obtained by him amounts to about forty-five per cent. Dr. De Garmo, however, calls attention to a condition not yet mentioned, in which Heaton's injection can be applied with benefit, and though properly belonging to the second division of the subject, can be alluded to here. It is that when recurrences take place after the radical operation for the cure of a hernia, they appear generally as comparatively small protrusions; these, and also small hernias of original formation can, sometimes, be treated successfully, and without compelling the patient to go to bed, by injecting five to ten minims of Heaton's fluid into the canal, after having had adjusted and worn for a short time previously a lightly applied truss. The amount of irritation sufficient to plug up the opening can, in this way, and while continuing the use of the truss, be accomplished by one or more repetitions, and yet allow the patient to attend without interruption to his business. I have resorted to this three times with benefit. I have not had any experience with Schwalbe's alcohol injections, concerning which this surgeon reports [1] 34 cases cured by this plan of treatment, but does not give the total number treated by him. He injects repeatedly (and this is important not only in this method, but also in Heaton's) a twenty to seventy per cent. mixture of alcohol and water; but Ranke, in the discussion that follows, stated that in over one hundred cases treated by him great pain was occasioned by the injections, and that it did most good in children and in small hernias in adults.[2]

From the foregoing statements it will be seen that there is but a comparatively limited range in the application of the injection method in the treatment of hernias. Indeed, one may say the very safety of this method allows it to be used in cases that should never be treated with the knife. But there is a very large number of old reducible hernias of considerable size, which are often painful and unsightly, and not always to be kept up by a truss, together with those that are more or less irreducible, and which oftentimes materially interfere with the pursuit of a livelihood, and which by temporary incarceration frequently threaten life, that appeal for surgical help. Although under the influence of antiseptic surgery, Steele, an English surgeon, was, in 1874, the first one to perform the radical operation for a large inguinal hernia, by suturing the ring after it had been exposed by an incision; yet it is rather to the efforts of Nussbaum and Riesel, in 1876, and of Czerny, Socin, and Schede, in 1877, that the credit is due of placing this operation on a firm footing in surgery. Since that time the exhaustive brochures of Leisrink [3] and Ségond [4] have collected and digested a large number of cases. To their figures can now be added a third collection, made by Joannes Andaregg,[5] an assistant of Socin's, in the Glarus Hospital. In this manner a total of 273 cases has been arrived at; but before considering the results obtained statistically, a description of the operative procedures adopted should be given. They consist, in brief, 1, in the antisepic exposure of the ring and upper part of the hernial sac by an incision three or four inches long; 2, the reduction of the hernial contents—if this is possible the sac is not opened; 3, the separation of the sac at its neck, and the ligation of it as high as possible after forcibly drawing it downward; 4, the cutting off and removal of the sac, unless the hernia be a congenital one, when a portion is left to be sutured so as to form the top of a tunica vaginalis; and finally, 5, the sewing together of the ring and a portion of the inguinal canal. The wound is thereupon drained, and more or less tightly closed and dressed. A few comments may be made on the various steps of this operation, and their possible variations and complications.

The exposure of the sac and treatment of its contents.—In coming down on the hernia, after rendering the parts aseptic by shaving, scrubbing, and disinfecting, more certainty will be attained and less delay produced, by deepening the incision, after going first through the skin and fat above the external ring until this latter is definitely made out and exposed, when the hernial sac can be more quickly and easily reached by tearing through the connective tissue at this point with two forceps, and its neck more readily encircled by the finger than by any other way. By stripping it now downward, it can often be peeled throughout from its attachments with great facility, and the more rapidly the sac is reached and lifted out of its bed, the less likely is suppuration to occur. In this way, also, is the detachment of it from the spermatic cord best accomplished. Occasionally this latter is by no means an easy task, especially in the congenital hernia, in which it is well known the peritoneal layer is more

intimately connected with the cord. The method of making a new and complete tunica vaginalis, already spoken of, has succeeded happily in my hands in two cases, the testicle moving freely in its finished sac. In a third case, instead of suturing the cut-off hernial canal or sac it was left open, and a drainage-tube carried out through the bottom of the scrotum; but this I deem, when the suture is used, unnecessary.

If it is possible to force the intestine or omentum in reducible hernias into the sac by pressure on the belly above, before the incision is begun, it should be done, as it not only renders the operation easier, but also allows one often to put in practice what I consider a proper surgical precaution, viz., the excision of the omental part of a hernia, which, by its abnormal length, tends to produce relapses. This point is not conceded by all surgeons, though in the cases where a mass of omentum has become irreducible by adhesions or by long dwelling in a sac, or where the omentum has undergone inflammatory or nutritive changes, there is no question now as to the proper treatment. In all such cases the omental mass is to be removed. This adds, it is true, somewhat to the risk of the operation, according to Andaregg increasing it by two per cent.; but as this risk is shown to be largely from a preventable cause, namely, hemorrhage, it can be thrown aside if certain precautions are observed. In the total collected cases of Andaregg, MacEwen, Banks,[1] Abbe,[2] and my own, amounting to 379 cases, there were 5 deaths from this source—hemorrhage. I have not had this mishap terminate seriously; but had I not adopted the precaution, which now I beg to present to you, I should have contributed possibly to this list of mortality. I had tied off, in several portions, with silk suture, which for this purpose is much safer than catgut, a mass of omentum, and had left attached to the remaining stump, after the removal of the herniated portion, the long ends of this ligature, to pull it out again from the abdomen in order to make a final inspection of it prior to closing the wound. And it was fortunate that this was done, for it revealed that quite a smart hemorrhage was going on from a portion of the omentum that had slipped at the edge of the flattened pedicle. An extra turn of silk around the whole mass made everything tight, and the further history of the case is given below.

Case I.—*Large irreducible congenital hernia (twenty-seven ounces); omentum cut off; Nussbaum's operation; cured.*—E. S——, aged thirty-two. He had from early childhood an irreducible tumor in the left side of the scrotum, which is now the size of a cocoa-nut, and is believed to be omental. Two years previously, during an attack of gonorrhœal epididymitis, swelling and fluctuation appeared, for which aspiration was resorted to, and three ounces of fluid withdrawn with benefit. Now the size of the hernia is so great that not only is its weight much complained of, but also its appearance subjects him to much mortification. April, 1884, under ether, an incision four inches long was made from over the internal ring downward and inward toward the scrotum, the sac reached and opened, and found to contain omentum mainly, with a single loop of small intestine three inches long. A number of adhesions existed, which were detached after being previously ligated. The intestine having been returned to the abdominal cavity, the portion of omentum corresponding to the neck of the sac was perforated and tied in three portions with heavy silk, and cut off. Some hemorrhage took place from the omental stump, which was recognized and demanded an extra ligature. The mass removed weighed twenty-seven ounces. The omental stump, with its ligatures still long, and guarded by a clamp attached to them, was allowed to drop into the peritoneal cavity, and the opening temporarily closed by an antiseptic sponge held in a long clamp. After this the sac was stripped from its connections, and in so doing the bare testis was lifted up, and proved thus the case to be one of congenital hernia. The lower part of the sac was, therefore, cut across, and the inferior mouth sewn together to make a proper tunica vaginalis. The upper part of the sac after the omentum had been finally inspected and its long ligature ends cut away, was now pulled down as far as possible and tied securely, as near as one could to the peritoneal level, with strong catgut. The part outside the last ligature was then cut off and removed, and the wound finally closed after a drainage-tube had been carried from the external ring outward, and another from the new tunica through the bottom of the scrotum. No attempt was made to sew together the external ring. Full antiseptic precautions were carried out during the operation, and similar dressings were snugly applied over the wound. The progress of healing was without note. Considerable pain, and temperature 101° for first twenty-four hours, after that normal. Patient got about in three weeks, wearing a loose truss, which he left off in six months. Hernia cured until March, 1886, when a slight bulging was noticed, size of a pigeon's egg, for which an injection of Heaton's fluid, five minims, was twice made, one week apart, the patient continuing at his business and wearing a truss all the time. Since then he has been able to omit a truss, and no recurrence has taken place.

The tendency to slipping of the outer edges of the omental pedicle, and of splitting an omental vein in transfixing it, can be guarded against by tying the mass in several sections, the outer ones being rather small, and finally encircling the already tied pedicle with a final turn of silk, tightly tied. Securing it in this manner, and making a final inspection before cutting short the ligatures and tying the hernial sac will, I fully believe, do away with this risk. Furthermore, if the sac should not be immediately tied off after the omental section or replacement of adherent intestines, the peritoneal opening should be temporarily plugged by an antiseptic sponge held securely in a clamp. This is important as it also prevents any fluid, blood, etc., running into the peritoneal cavity.

The formation of a complete tunica vaginalis is illustrated in

Case II.—*Strangulated congenital inguinal hernia; ligature of sac.*—W. K——, aged sixteen, operated on December 16, 1884. Three days previously, while lifting, a painful swelling appeared in right groin, which soon descended to the scrotum; vomiting soon came on and has persisted to the present date. His condition when observed was fair; temperature 98°; pain great; vomiting not stercoraceous. He was immediately etherized and taxis mildly employed. This failing, an incision down to and into sac was made, revealing a loop of small intestine deeply congested. Constriction was mainly at external ring, and less so at internal opening. These were nicked by a straight, blunt bistoury, intestine replaced, and sac tied and cut off as high up as possible, and again tied at a lower level to make a tunica vaginalis, for the hernia was a congenital one. No sutures to external ring; two rubber drains inserted, one into external ring and one at lower angle of incision. In six days primary healing, except at tube openings. Discharged from hospital, with a pad over external ring, and directions to procure a truss and wear it.

It may happen that such dense adhesions exist of the sac to the cord that a portion of the former must be left. This is of no moment if sufficent of the neck of the sac remains to be tied off; but adhesions of the intestine to sac-wall may at times be so extensive and so intimate as to preclude their dissection. Another interesting peculiarity was met with in

Case III.—*Double scrotal hernia; contents of left side of large intestine simulating adhesions.*—W. S——, aged sixty-two, with a large double scrotal inguinal hernia of twenty-five years' duration, with rather large rings, inter-

[1] Banks: Notes on the Radical Cure of Hernia, Medical Times and Gazette, July 5, 1884.

[2] Abbe: On the Radical Cure of Hernia, read before the Medical County Society, New York, January 25, 1886.

fering with patient's business as a pedler. Heaton done on both sides, February, 1885; left one soon returned, and injection was repeated as patient declined radical operation. The right hernia remained cured, but left one returned fifteen months later, right one still remaining up. Radical operation done on the left side, May 22, 1886. Three-inch incision, ring carefully exposed on upper surface, and as intestinal contents of sac were apparently adherent, it was opened, when it was discovered that it was a herniated large intestine, with its adjacent parietal peritoneum. This was returned as far as possible, after stripping up the sac, into the abdominal cavity, and the ring, which was large, admitting three fingers, was carefully brought together with three silver-wire sutures, and wound packed with iodoform gauze and allowed to heal from bottom to get a more solid cicatrix.

Patient eloped from hospital with sinus at operation wound, June 9th, and has not since been heard from.

Banks [1] reports a case similarly treated, with a good result, and gives a caution against mistaking the condition for intimate adhesions and thus acting erroneously.

In another case where the adhesions were broad and close, a strip of the sac was put back attached to the intestine without mishap.

The complication of an undescended testis associated with a hernia was encountered in the case next presented.

Case IV.—*Reducible inguinal hernia; MacEwen's operation; removal of an undescended testis.* — B. E. T——, aged twenty-five, had a hernia in right scrotum which has existed nearly twelve years, and which cannot be controlled by a truss. It is painful, and he asks surgical relief. The swelling is the size of a goose egg. Testicle on right side wanting.

Operation November 6, 1886.—Hernia sac contained intestine and an atrophied testis, which lodged, when reduced, in the inguinal canal. This was only one-half the size of a normal testicle, and it was drawn down and its cord tied off with catgut. The sac was then stripped up to internal ring, and the parietal peritoneum peeled off for a space of one and a half inch above the ring, and the sac, crumpled up by a catgut cord piercing it to and fro several times, was drawn up into this space and secured by carrying the terminal portion of the cord through the abdominal wall muscles. The pillars of the ring, as high up as possible, were then sewn together as advised by MacEwen, and the upper half of the wound left to heal by granulation under a packing of iodoform gauze, the lower portion being closed by two gut sutures. Progress without temperature; by December 9th he had left the hospital, wearing a sticking-plaster compress, and up to date of January 15th is free from recurrence.

A further direction is necessary relative to omental adhesions existing at the neck of the sac, or mouth even; they should be separated carefully by the finger, so that the stump can drop freely into the peritoneal cavity, or else you may have an inclined plane of this tissue directing intestine or other omental masses toward the closed aperture. Indeed, it is for this reason that Banks advises, in all instances, the opening of the sac, so as to explore it and to satisfy one's self in this way beyond peradventure that no small mass of adherent omentum at the mouth should escape detection and liberation. Individually I have found that it is not necessary to open the sac when it has been found empty or its intestinal contents have been reduced by palpation, with or without invagination of it. I have been fully able through its thin walls to determine whether the mouth is free, and particularly is this so in the more liberal manipulation of the sac now practised in the method recommended by MacEwen,[2] and which will shortly be detailed.

The treatment of the sac.—Usually, as practised by the German surgeons, I have, after separating the sac from its connections, pulled it down as far as possible and tied it, without transfixion, with a heavy catgut ligature (see Fig. 2), with only once a slipping, from cutting the sac beyond too close to the ligature; the open ring of peritoneum was in this instance seized with a forceps, gathered together and tied higher up. This pulling down and tying the sac off at the peritoneal level has, as is known, the intent of obliterating the funnel-shaped depression at the internal ring and thus to prevent the tendency to relapse; but the few post-mortem examinations made some time after such an operation have shown that this is not always successful. Ségond has collected six such observations (Schede, Riesel, Weinlechner, Reverdin, Czerny, and Esmarch). In three of these there was either a dimpling in of the peritoneum sufficient to admit the end of the little finger, or a funnel-shaped depression or radiated folds of peritoneum found at the internal ring. In all, however, was the canal completely obliterated. A corroboration of the complete occlusion of the canal and internal ring I can offer in the history of Case V., who died of pneumonia and chronic nephritis twenty-two days after the operation, but with her wound practically healed.

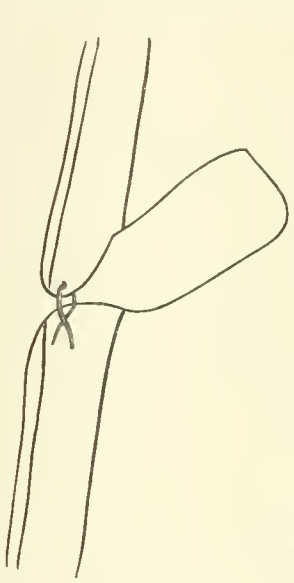

Fig. 2.—Tying Neck of Sac close to Internal Ring. (Nussbaum, Czerny.)

Case V.—*Large incarcerated inguinal omental hernia.*—M. S——, aged sixty, entered the New York Hospital October 1, 1886, with an omental hernia of the right inguinal region nearly eight inches in diameter, which had existed for ten years, but which had become irreducible within the past seven days. There was some heat and swelling present, with fluctuation in the swelling. On aspiration several ounces of bloody serum were withdrawn. No constitutional symptoms of strangulation.

October 9th.—Mass was split open and eight ounces of bloody serum evacuated, and a quantity of omentum, weighing three hundred and sixty-six grammes, inflamed and hardened, tied, with a strong silk ligature in two places, and again by a third silk ligature encircling the whole. It was then cut off beyond these ligatures and removed. The thickened hernial sac was also removed after high ligation. The ring was sewn up with heavy catgut as high as possible, and the wound closed, after being duly drained, with antiseptic dressings. It did well, and by the 27th only a slight ulcer at site of tube was left, and patient was sitting out of bed.

October 28th.—Slight chill, temperature 102°, and examination of chest showed pneumonia to be developing, which, with the chronic Bright's disease she had, caused death on 31st.

The peritoneum showed, on section through the operation wound in the abdominal walls, everything solidly united, and in the abdominal cavity the omentum was tightly united to the parietal peritoneum about the internal ring, and also to a portion of ileum and large intestine. The internal ring in being dissected was found also closed.

The frequent recurrences or relapses after the radical operation for hernia, however, show that its technique is yet far from perfect. Andaregg, whose collection of results is the best observed, gives 105 cases under his own observation where the patients have been inspected from periods ranging from seven months to seven years, with 64 definite cures, or sixty-one per cent. Of the 41 cases that relapsed 29, or thirty-nine per cent., took place in the first year, 8 in the second year, and the rest later. The

[1] Cit. supra.

[2] Cit. infra.

relapses were usually slight, and had little disposition to increase, and were easily controlled by a truss; with large old hernias and double ones relapses were more frequent. The above figures, however, embrace radical operations done in both strangulated and non-strangulated hernias. A further examination is therefore necessary, and shows that in 41 cases of non-incarcerated inguinal hernias there were 21 relapses, or fifty-two and one-half per cent., and in 6 cases of femoral hernia there was 1 relapse, or 16.6 per cent., certainly a less encouraging showing than the first grouping of figures. Rather remarkable, too, is the circumstance that in strangulated hernias, while the employment of the radical operation does not materially increase the risk, it adds decidedly to the chance of a complete cure of the hernia, as the relapses were only twenty-seven per cent. in a total of thirty-three inguinal hernias. Out of my own 21 cases in which the radical operation has been done, including 4 cases of strangulated hernia, I have been unable to trace more than 11 of them beyond a period of eight months, owing to many being hospital, *i.e.*, migratory patients; of these there were 8 cured. Neither do I find assistance on this point in the interesting papers of Banks and Abbe, already alluded to. It must be confessed that the frequent recurrence of a hernia after the radical operation justifies the opinion of Ségond, that "it is an operation which in the majority of cases only triumphs over an irreducible or unmanageable hernia, and renders it controllable."

The latter part of this dictum is corroborated by Leisrink, who shows that eighty per cent. of the relapsed cases have marked improvement in their hernias from the operation, and he therefore advises surgical interference on this ground. An improvement in the mode of operation, with a corresponding increase in the percentage of cures, has quite recently been published by MacEwen,[1] of Glasgow, by which, in 25 cases of free inguinal hernias that were under observation from periods varying from eight months to five years (17 were over one year) there were only 9 relapses, or thirty-six per cent.

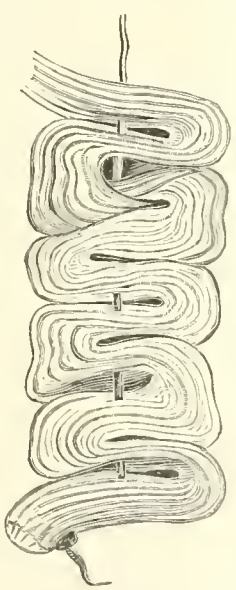

Fig. 2.—Folding Up the Hernial Sac. (MacEwen.)

MacEwen has had also a corresponding success when joining the radical operation to the treatment of a strangulated hernia, and gives 23 cases (14 inguinal and 9 femoral), with 1 relapse, or 4.3 per cent., the cases continuing under observation from eight months to four years after the operation. This is, indeed, a decided improvement in the cure of the affection under consideration, and is apparently accomplished by two deviations from the usual treatment, the first of which is his peculiar treatment of the sac. Instead of tying this and cutting it off after separating it from its attachments, and after emptying it of its contents, he secures it, in his own words, by "a stitch firmly at the distal extremity. The end of the thread (catgut) is then passed in a proximal direction several times through the sac, so that when pulled upon the sac (see Fig. 3) becomes folded on itself like a curtain. The free end of this stitch, threaded in a hernial needle, is made to traverse the canal and to penetrate the anterior abdominal wall about an inch above the internal ring, the wound in the skin being pulled upward so as to allow the point of the needle to project through the abdominal muscle without penetrating the skin. The thread is relieved from the extremity of the needle when the latter is withdrawn. The thread is pulled through the abdominal wall, and when traction is made upon it, the sac wrinkling upon itself is thrown into a series of folds, its distal extremity being drawn farthest backward and upward. An assistant maintains traction upon the stitch until the introduction of the sutures into the inguinal canal, and when this is completed the end of the stitch is secured by introducing its free extremity several times through the superficial layers of the external oblique muscle. A pad of peritoneum (see Fig. 4) is thus placed upon the abdominal side of the internal opening." To accommodate this wrinkled-up pad MacEwen previously strips up the parietal peritoneum for half an inch around the whole abdominal aspect of the circumference of the internal ring. This peritoneal pad, made up of wrinkled up sac, is supposed to constitute a boss or bulwark, with its convexity presenting backward toward the abdomen, while its base rests on the abdominal walls surrounding the circumference of the internal ring. This not only protects the internal ring, but sheds the intestinal wave backward away from the opening.

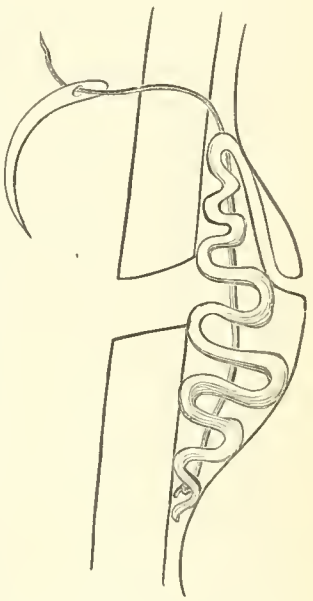

Fig. 4.—The Subperitoneal Tucking Up of a Folded Hernial Sac. (MacEwen.)

My own experience with this procedure embraces only six cases, and the results are too recent to determine for myself its value. In all but one case it was easy to accomplish the desired reposition, and in one patient who had previously submitted to the radical operation after the usual method of pulling down the sac, tying it off, and suturing the external ring, the statement made by him that after the last operation (MacEwen's) "he felt tighter than he had done for years," testifies in its favor.

The closure of the ring or canal.—Socin[1] does not consider the suturing of the ring of special advantage, and apparently proves it by showing that in 39 cases of inguinal hernia where no suture was used there were 16 relapses, or thirty-eight per cent., and that in 32 cases where it was used there were only 12 relapses, or thirty-eight per cent. He says that where the suture is not used the patients get well quicker and do better. This also I have observed. Yet, in the words of Czerny, so long as it is uncertain whether it is the treatment of the sac or of the ring and canal that is important, it is better to use both procedures. Hence most surgeons, since 1881, when Czerny, through his assistant Braun,[2] gave his second series of cases to the world, have, after removing the sac in an inguinal hernia, sewn the ring, and to some extent the canal also, snugly up to the cord in the male, and to the round ligament in the female; but when a femoral hernia has been encountered, generally speaking, only the sac has been removed and no attempt made to close the opening, mainly on account of the supposed danger of implicating the femoral vein. MacEwen, however, has given, in his remarkable cases, 9 instances of femoral hernia where not only was the wrinkled sac used as above described, but also in 8 cases the falciform process was sutured to Gimbernat's ligament, with eight permanent cures.

It is admitted, I may state, that aside from the question of closing the femoral ring, a cure is more apt to occur in this variety of hernia than in an inguinal one.

[1] W. MacEwen: On the Radical Cure of Oblique Inguinal Hernia by an Internal Abdominal Peritoneal Pad, etc., Annals of Surgery, August, 1886.

[1] Also, Israelsohn, Anderan, Leisrink, and Reverdin advise its not being done.
[2] Berlin. klin. Wochenschr., No. 4, 1881.

To close the canal, if such exists, or the space between the overlying rings, from one to four sutures in inguinal hernias have been employed, and of either carbolized silk, silver wire, or catgut. The majority of operators now use heavy catgut, either chromicized, as lasting longer, or the ordinary aseptic gut. Banks prefers heavy wire knotted, not twisted. I have resorted to both silk and wire, and have found persistent fistulas left from their use, and can show here several silk strands which had been discharged after being retained over eight months, and one which eventuated in a fecal fistula, which, however, soon closed after the casting off of the suture. Wire has played in my hands the same trick. One of Andaregg's objections to the wire sutures is rather fanciful. It is that they cause gaps by splitting the fascia through which they are passed, and also render the ring opening jagged by their cutting out, as, according to him, they all do.

Like others I have felt for some time that the mere suture of the external ring was unscientific as well as unsatisfactory, yet I had not the courage of Riesel, who, in 1877, boldly advocated the splitting of the inguinal canal its whole length, and after taking out a portion of it, to suture it from the internal ring downward, and gave subsequently 12 cases thus operated on, with only 1 relapse.

The first case of hernia I attempted to operate on was on the person of a patient in Bellevue Hospital in 1882, and in this, through a faulty idea of Czerny's procedure, I was led to do the imperfect operation of only tying off a part of the sac, and closing the ring by sutures. Descent of the hernia took place through the narrowed ring, and strangulation occurred, which, under the dressings, was mistaken for peritonitis, and was not recognized till too late. This led me to hesitate to use the ring suture in two subsequent cases, which, however, did well (Case I. is one of them). After that I employed it in nearly every case of inguinal hernia, going as far up as I could for the top suture, and putting in two or three sutures in each case, and inserting a drainage-tube between the last suture and the spermatic cord and within the canal. Sometimes a suture of fine catgut held the distal end of the tube in position. This was done to avoid, if possible, the suppuration which the frequent tearing up of the connective layers external to the sac often produced, and which has become limited in its occurrence, since the sac has been reached and enucleated, as already described. In watching, however, with interest and some anxiety, those cases where the suppuration seemed to be deep in the canal, and about the subperitoneal region of the internal ring, it was found that the cicatricial hardening thus resulting was of benefit in offering an additional barrier to the recurrence of the protrusion. Hence, early in 1885, I purposely changed my method of operating so as to leave the wound entirely open over the external ring, and to stuff it with iodoform gauze, and only to close it at the lower angle by one or two sutures. In this way, by the firm cicatrix thus produced, I have added, I fully believe, another barrier to the return of the rupture, and the recent publication, by Nussbaum,[1] of the suggestion to bring about repair by granulation over the ring by the application of the actual cautery, confirms me in its value.

With the exception of Riesel's plan, MacEwen's mode of closing the enlarged canal seems to me the best, and in the case of his plan of operation it has been easily accomplished. Not only are the sutures applied higher up the canal than usual, but in such a way as to drag the inner edge of the conjoined tendon under the outer pillar of the ring of Poupart's ligament, and so interpose a valvular obstacle to the recurrence of the hernia. A glance at Fig. 5 will show how this is done. After the sac has been returned to the abdomen and secured to the abdominal surface of the internal ring, the finger is passed into the canal to make out the inner and lower borders of the internal ring, and feel the pulsation of the epigastric artery, so as to avoid puncturing it. A threaded hernia-needle, Fig. 6, or a stout, curved Hagadorn needle in its proper holder, is then introduced, and, guided by the index-finger, is made to penetrate the conjoined tendon high up toward the internal ring, in

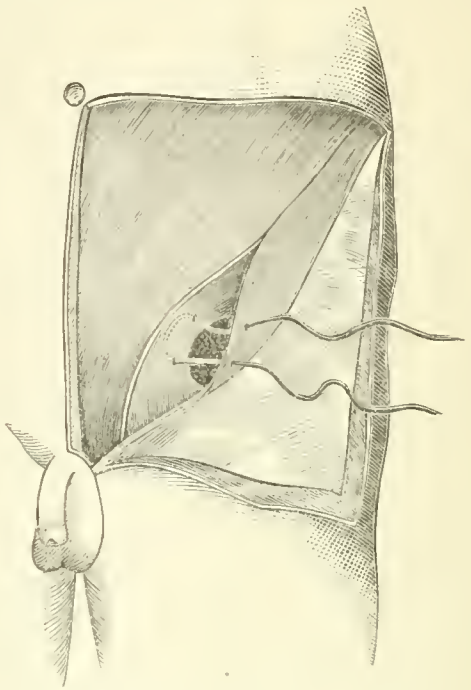

FIG. 5.—Schematic Closure of Inguinal Canal. (MacEwen).

two places about three-fourths of an inch apart, in such a way that the loop is on the under surface of the tendon and the free ends are on the upper side. These free ends are carried across the ring and canal (as one end is now without a needle, it should now be attached to one) and introduced from within outward, the lower one through Poupart's ligament, and the aponeurotic structures of the transversalis, internal and external oblique muscles, and the upper one through the transversalis internal and external oblique muscles, at points corresponding in height with the threads in the conjoint tendon. The suture is completed by drawing the free ends and tightly tying them together with a double reef-knot. In adults it is well to repeat the suture lower down the canal, and the pillars of the external ring are likewise brought together. Care is to be taken that the spermatic cord be left freely movable. MacEwen, from whom the above description is mainly taken, advises not tying the sutures until after all have been applied and tested. He further directs a drainage-tube to be inserted and the wound closed. I have, as before stated, preferred to leave the part of the wound over the ring open. Antiseptic dressings of iodoform dusted on sublimated peat-bags or gauze dressing are carefully secured by bandages, and kept on without change, if the case progresses favorably, for ten to fifteen days, or until stained. After healing has been accomplished the patients are allowed to get out of

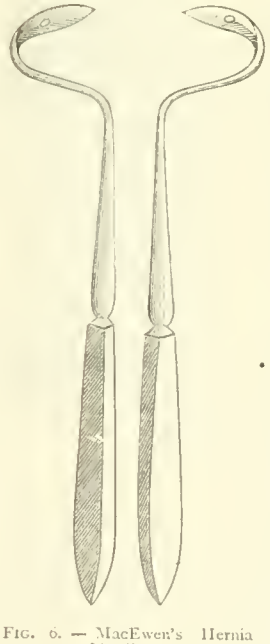

FIG. 6. — MacEwen's Hernia Needles.

[1] Nussbaum: Ein neuer Versuch, zur Radikaloperation der Unterleibsbrüche, Centralblatt f. Chirurg., No. 24, 1886.

bed, this is usually done in about four to six weeks. They are advised to wear a compress, best made of superimposed layers of sticking-plaster and bandage, and later on a light, flat, broad truss. Heavy work should not be undertaken until past the third month. Concerning the subsequent use of a truss Andaregg directs that none should be worn unless the relapse actually occurs, as it not only causes stretching of the peritoneum and absorption of newly organized tissues, but also advises free muscular movements, particularly those affecting the abdominal muscles, that thereby the orifices and canal could be strengthened. I much prefer the safety of a *flat*, and therefore innocuous truss, and advise my patients to wear such from three to six months; undue pressure must be avoided.

It will be noticed by those who have followed me thus far that the important point as to the risk of this operation has not yet been more than touched upon, and, after all, the question hinges upon this point, for if any considerable danger exists in an operation which can be promised as curative in but a comparatively small proportion of cases, it should not be often resorted to in the treatment of an affection which is in itself not directly hazardous. Looking at the grand total of the cases collected by Andaregg, which include those of Ségond and Leisrink, there were 273 cases of free or non-strangulated hernias, with 12 deaths, 4 of which were from preventable hemorrhage, 8 from septic complications. Joining to these the statistics of others we have the following summary:

Andaregg, 273 cases of radical operation of free or non-strangulated hernia, 12 deaths (4 from hemorrhage) or 4.39 per cent.; Abbe,[1] 16 cases, 2 deaths (1 from hemorrhage); Banks, 36 cases, 1 death; Weir, 17 cases, 1 death; MacEwen, 33 cases, no death; total, 379 cases, with 16 deaths, or 4.22 per cent.

From these can justly be taken those dying from hemorrhage, since increased experience has taught how this is to be avoided, when the mortality will be seen to reach only to 2.90 per cent. Of the 36 femoral hernias operated on there were no deaths.

This is sufficiently low for surgeons to be warranted in carrying on the operation, which, as is seen by MacEwen's statistics and plan, is becoming more simple and less dangerous, and, in fact, when performed in healthy individuals, as is shown by analysis of Andaregg's cases, it is found that of 125 cases operated on between the ages of eleven to forty, only 2 died—1.6 per cent.—the mortality under and over that limit being 8.3 and 8.1 per cent. respectively. The size of the hernia, as his collection also shows, as well as the age of the patient, influences the mortality to a decided degree.

In concluding, the considerations expressed at length in the foregoing pages lead me to the following recapitulation:

1. That small reducible and easily controlled inguinal hernias can with safety be treated with Heaton's injection, and with a reasonable prospect of success—thirty per cent. of recoveries.

2. That in similar hernias in children, in which the use of a truss has failed, Heaton's injection is to be recommended as a particularly successful procedure.

3. That in unmanageable, painful, or irreducible hernias, demanding surgical interference, and sometimes those in which Heaton has failed, the radical operation should be resorted to, with the sac tucked up or tied off, as the surgeon may determine, but with a high and complete suturing of the canal.

4. That where omentum is found in a hernia it should be securely tied and resected.

5. That the wound in the region of the external ring should be healed by granulation to afford a cicatricial barrier, as an additional factor in the cure.

[1] Dr. Abbe has informed me that his cases up to January 31, 1887, amount to 36 inguinal, 10 femoral, and 4 umbilical, with 3 deaths—1 from hemorrhage, 1 from intestinal band strangulation, and 1 from sepsis, from a simultaneous varicose vein operation. His last 40 cases have been without a single fatal result—9 were done according to MacEwen's method.

ON THE ADAPTATION OF CORNING'S METHOD OF PRODUCING LOCAL ANÆSTHESIA BY COCAINE TO OPERATIONS ON THE EYELIDS.

By DAVID WEBSTER, M.D.,

NEW YORK.

Since Koller's publication of his discovery of the anæsthetic properties of cocaine when applied to mucous membranes, I have rarely given ether, in cases of adults, for the performance of any operation upon the eyeball or upon the tissues reached through the conjunctiva, except in cases of enucleation. I have constantly used cocaine in my cataract extractions, keratonyxes, iridectomies, paracenteses, in tenotomies of the interni and of the externi, in advancements of these muscles, in the removal of pterygia, and of tumors of the cornea and of the conjunctiva, in the excision of chalazia, and in the various operations upon the tear-passages, and in the removal of foreign bodies from the eye. In all these operations the anæsthetic effect of the cocaine has been most satisfactory. On several occasions I have performed operations involving the skin of the eyelids after having injected a solution of cocaine, hypodermatically, into the parts to be operated upon. The results were unsatisfactory. There was always not only so much swelling of the subcutaneous tissues, produced by the necessary traumatism and by the presence of the fluid, as to embarrass the steps of a delicate operation, but in every case the patient seemed to suffer nearly as much pain as though the operation had been done without an anæsthetic. I therefore reluctantly abandoned the use of cocaine in this way, and returned to the use of ether for my lid operations. It seemed to me highly improbable, not to say impossible, that any painless process would ever be discovered by which the skin and its underlying tissues could be anæsthetized, without swelling and with uniformity, over any desired area. Great was my surprise, then, as well as my delight, when my friend, Dr. Corning, demonstrated to me, upon my own person, that he had solved the problem. Several days later the doctor published an account of his method in the *New York Medical Journal* (vol. xliv., No. 19). I have no doubt that many of you have read the paper referred to. You will recollect that he found three things necessary to produce the desired effect.

1. An instrument for making multiple punctures of the skin, the use of which is painless and bloodless;
2. A galvanic battery; and
3. A solution of cocaine.

The portion of skin which it is desired to anæsthetize is first punctured by the use of the instrument, which makes many punctures at once, about a millimetre apart, the only sensation felt being that of a slight blow or concussion. A sponge saturated with a solution of cocaine, four per cent. if you like, and attached to the positive pole of a galvanic battery, is then placed in contact with the punctured skin, while the negative pole is brought in contact with some other portion of the patient's body, and five or six cells of the battery are turned on. After the application has been kept up five or six minutes the skin is found to be completely and uniformly anæsthetized. The anæsthesia may be carried to any depth, down to the bone if necessary, by removing the sponge and driving the needles in deeper, and then reapplying it for a time. Of course, it only remained for me to adapt this method to operations upon the eyelids, and to accomplish this the only thing that was necessary was to have a more delicate puncturing instrument made. At my request, and according to my instructions, Messrs. John Reynders & Co., of New York, made such an instrument, which I have already used in several cases with entire satisfaction. I shall report these cases further on.

The multiple-puncturer which I had constructed, and of which a wood-cut is here inserted, is of about the size of a hypodermic syringe. It consists of one hundred and fifty needles, which may be made to project from

a hollow cylinder to any desired length by means of a regulator, and a spiral spring within the cylinder, controlled by the handle.

Before using the instrument upon the eyelids, the conjunctiva should first be anæsthetized by dropping in a solution of cocaine in the usual way. The lid should then be raised a little from the eyeball by means of the little

finger, or a hard rubber spatula, so as to prevent any concussion of the globe. In puncturing the skin at the outer canthus, preparatory to the operations of canthotomy, cantholysis, and canthoplasty, I have found that I could best protect the eyeball from concussion by inserting the end of my little finger beneath the junction of the lids at the canthus and making gentle pressure so as to lift the parts slightly from the eyeball. A hard rubber spatula could easily be made suitable for this purpose. On using the instrument the needles should be drawn up out of sight into the cylinder by means of the handle (*c*), the end of the cylinder placed in contact with the skin, and then the handle let go. The bunch of needles strikes the skin with a slight thud and without any sensation of pricking or pain. The whole surface to be involved in the operation should be thus pricked over, and then a solution of cocaine (I have always used a four per cent. solution) should be driven through the punctures by galvanism as above described.

My first experience with the use of this method, other than that upon my own arm, was in the removal of a small tumor situated at the juncture of the lower lid with the cheek immediately below the outer canthus, on December 30, 1886. The patient was a gentleman, twenty-four years of age, and a journalist by occupation. He said the tumor began by a small "cake of flesh" which he picked off with his finger-nails about March 1, 1886. This re-formed and was picked off about five times before June 1st. Since that time he had let it alone, and it had continued to increase in size, rather slowly at first, within the last few weeks more rapidly. When he came to me it seemed about the size of a large pea. Its surface was smooth, unlike that of a wart, and I suspected that I had to deal with an incipient epithelioma. With Dr. Corning's assistance the parts about the growth were anæsthetized by his method, and the growth was removed and the wound closed by a suture without any manifestation of pain on the part of the patient, who also stated positively that although he felt every step of the operation it gave him absolutely no pain. As I did not intend to cut the growth I did not puncture it, but punctured all around its base where the incisions were to be made. The patient returned on the second day after and had the stitch removed. There was primary adhesion and only a slight linear scar.

The growth was examined by Dr. Ira Van Giesen, pathologist to the Manhattan Eye and Ear Hospital, who, on December 30th, reported as follows: "The tumor is ellipsoidal in shape, long axis 1 ctm., the other two axes 4 and 6 mm. It is invested by normal integument. Beneath this integument the tumor consists of large round-cells and large fusiform cells, with scanty basement substance and scantily supplied with blood-vessels. The anatomical diagnosis is, then, large round celled and large spindle-celled sarcoma."

My second operation with the use of this method of local anæsthesia was a cantholysis upon the left eye of a boy, aged sixteen. This youth had been the subject of granular lids and pannus since two years of age, and consequently was not well developed intellectually. He had been under constant treatment for his eye affection at the public institutions of New York nearly all his life. He came to the Manhattan Eye and Ear Hospital on January 5, 1887, when his vision was tested and found to be reduced to $\frac{4}{200}$ in the right eye, and $\frac{1}{200}$ in the left. After applying cocaine until pricking the skin with a pin did not hurt him, I made the usual cut at the outer canthus with scissors. He began to cry. I asked him what was the matter, and he said, "You are cutting my eye." I soon reassured him, however, and proceeded to finish the operation. There were no further manifestations of pain, and after the operation was over he admitted that it did not hurt him at all, but that he began to cry because he was frightened. When I performed the same operation upon his right eye, one week later, having used the cocaine in the same way, he gave no signs of pain from beginning to end. His vision and the condition of his eyes have improved very markedly since the operations, showing that the use of the anæsthetic in this manner has no injurious effect upon eyes with granular lids and pannus.

Of course, this method of producing local anæsthesia is not likely ever to come into general use in operations upon the eyelids of children or of timid adults. No matter how painless the process, and how thoroughly the parts are anæsthetized, such patients will always be frightened and rendered more or less uncontrollable by their consciousness of being cut, and by seeing the instruments as they are used about the eye. These objections will always hold good as regards all methods of local anæsthesia, and the class of patients referred to will, probably, always have to be put to sleep for the performance of surgical operations about the eye.

ACUTE EPIPHYSITIS OF THE HIP.[1]

By V. P. GIBNEY, M.D.,

NEW YORK.

On February 12, 1885, while attending some cases at the Nursery and Child's Hospital, Dr. Hance, the House Physician, asked me to see a well-nourished, bright little girl who was running about the ward. The child presented a decided limp, which was due to shortening of the left lower limb. There was no evidence of pain or tenderness, and seemingly there was no stiffness.

The history was given me at the time, and since communicated in writing, by Dr. Hance, to whom I am indebted for the specimen, that the child was born now four years and three months ago, and was a strong, healthy baby. When six or eight months of age—dates not recorded—she suffered from a large acute abscess of the hip, which opened and discharged for a number of months. There was no history of any traumatism. The sinus closed spontaneously, and the little patient was walking about by the aid of a chair when she was two and a half years of age.

My examination, two years ago, shows that the child walked with the left foot everted over nearly a quadrant, the limb being well rotated outward, and that the limp was quite marked. There was three-quarters of an inch shortening, but this amount was easily overcome by traction. On the anterior surface of the thigh, upper third, was a cicatrix about half an inch in length and seemingly of long standing. The trochanter major was at least three-quarters of an inch above Nelaton's line. Flexion was made easily, and without any resistance, to an acute angle—the full extent that sound limb showed. Extension was equally easy, but abduction was limited to one-half the normal arc. The head of the bone could not be recognized by palpation. Grating and crepitation in the joint were very marked. There was no atrophy, and there were no acute symptoms.

For the past eighteen months she has been in a most miserable condition, suffering from repeated attacks of inflammatory diarrhœa. During the last summer she had true lienteric diarrhœa. Early in January of present year she developed tubercular meningitis, from which she died.

[1] Read before the Section in Surgery, New York Academy of Medicine, February 15, 1887.

The autopsy confirmed the diagnosis. A few scattered tubercles were found in each lung.

The specimen, when sent to me, consisted of the upper fourth of the femur and a portion of the pelvis, which was supposed to include the acetabulum. The section, however, seems to have mutilated the capsular ligament, and I am unable to learn just how much of the capsule was destroyed by the morbid process. The unnatural mobility was well demonstrated, however, and the upper end of the femur slipped up and down over a very irregular cartilaginous surface. The upper rim of the acetabulum seems to have been destroyed, or, at all events, worn down into an irregular ridge. There was a very poor substitute for a cavity.

On removing what remained of the capsular ligament, adhesive bands were found passing irregularly from the two cartilaginous surfaces, showing the remnant of a very active arthritis. On vertical section of the femur there was found no vestige of an epiphysis, and the upper extremity of the diaphysis was covered by an irregular cartilaginous layer, probably the epiphyseal-cartilage disk. The diaphysis showed no signs of recent or old inflammation; and Dr. Thatcher, Pathologist to the Laboratory of the Polyclinic, pronounced the bone, to every appearance, normal. The medullary coats seemed also normal.

The specimen was not examined microscopically, because it was thought that nothing would be discovered that was not recognized by the naked eye, especially as so long a time had elapsed between the original inflammation and the death of the patient. I have seen, within the past ten years, a number of cases giving the clinical history presented by this case, but I have not had an opportunity of securing post-mortem appearances, except in a case presented by Dr. Jackson.

Following some European observers, I have been in the habit of designating such cases acute epiphysis. By reference to a paper "On the Acute Arthritis of Infants," published by Mr. Thomas Smith, in the "St. Bartholomew Hospital Reports" for 1874, I find ten cases in which the hip was the joint affected.

All were in children under one year of age, and in seven autopsies the bone-lesions described were: "Ragged hole opposite digital fossa in great trochanter, leading to subarticular abscess," in Case III. of series; "rim of acetabulum destroyed, . . . head and neck of femur gone," in No. IV.; "head gone, . . . cartilage of acetabulum here and there destroyed," in No. V.; no section made in No. VI.; "one-half of head of femur destroyed and free surface spotted over with punctiform ulcerations, one of which led to an abscess in cancellous portion of bone, acetabulum shallow and widened, sharp edge absorbed," in No. VIII.; "head and upper part of neck gone, diaphysis eroded," in No. IX.

Mr. Smith remarks that the "existence of subarticular abscess was first discovered by accident in making a section of the bone. I cannot doubt that in times gone by, when I was unaware of this peculiar pathological condition, I overlooked many instances of subarticular abscess from neglecting to make sections of the bone in cases of suppuration within the joint-cavities."

Mr. Macnamara in his former edition employed the terms acute epiphysitis, but in the last edition—1887—of his work on "Diseases of Bones and Joints" substitutes the terms "acute osteitis of infants."

Before the epiphyseal cartilage in infant life has formed, the centre of ossification for the epiphysis is within the synovial membrane, and hence inflammation beginning here rapidly invades the joint.

Sulphur in Chlorosis.—Dr. Paul Strübing and Dr. Hugo Schulz, of Greifswald, state that in a certain class of cases of chlorosis, in which iron and arsenic fail, the continuous use of sulphur is efficacious. In those cases, however, in which there is a catarrhal condition of the digestive tract it should not be used.

THE EMPLOYMENT OF MERCURY IN PARASITIC CONTAGIOUS DISEASES, MORE ESPECIALLY THE USE OF THE BICHLORIDE IN THE TREATMENT OF DIPHTHERIA.

By J. A. S. GRANT-BEY, A.M., C.M., M.D., LL.D.,

SENIOR SURGEON TO THE EGYPTIAN GOVERNMENT RAILWAY ADMINISTRATION; MEDICAL ADVISER TO HER BRITANNIC MAJESTY'S CONSULAR COURT, CAIRO; COMMANDER OF THE IMPERIAL ORDER OF THE MEDJIDIEH; CHEVALIER LAUREATE AND CROSS OF MERIT OF THE SOCIETY "CHEVALIERS-SAUVETEURS DES ALPES MARITIMES," ETC.

The following paper has been drawn up with the view of eliciting the opinions of other physicians, and is therefore not at all exhaustive of the subject.

Long before the profession had the slightest suspicion of the important part played by microbes in the production or aggravation of disease, mercury, in some form or other, had been employed, and found to be a powerful rectifier of deranged action in the human organism, but more especially in those diseases that experience and modern scientific research have since shown to be infectious or contagious.

Need I refer to syphilis and to the various parasitic skin diseases that are effectively cured by preparations of mercury?

This is known and carried out in the practice of every intelligent physician. But there are some parasitic diseases so insidious and so rapid in their progress to a fatal issue, that it is absolutely necessary, in using this drug, to have recourse to the most potent chemical combinations of it.

It is now many years since the physicians in India, in their treatment of cholera, discovered that frequently repeated small doses of calomel gave better results than any other treatment that had previously been tried.

But as the profession in India are not encouraged (rather the reverse) to look upon this malady as a parasitical contagious disease, we cannot expect any further development of this treatment on these lines.

To show how prejudice influences our practice, I need only refer to the fact that not long ago, when Englishmen travelling on the continent of Europe fell ill with typhoid fever, English physicians were sent to prevent the continental doctors from giving calomel. I don't mention this as being myself an advocate for giving calomel in every case and in every stage of typhoid fever; but the fact that calomel has been used extensively as a remedy in this disease by the continental doctors is a proof that they, in their experience, considered that it had a beneficial effect, and I have little doubt that what alarmed the English physicians was the exaggerated reports they had heard as to the continental use, or abuse, of calomel in the treatment of typhoid.

If typhoid fever is a parasitical malady, then certainly it comes under the category in which mercury would be employed in the treatment, and if calomel has been proved to be effective on the continent of Europe, its benefit must have been derived from its parasiticide action, and to have that action it need not be given but in very small doses.

Sometimes a loaded tongue and a gorged portal system call for a large purgative dose of calomel, and mistakes may have been made in giving such doses during the later stage of the disease when the intestine was extensively and deeply ulcerated. But even this condition of the bowel does not contraindicate the intelligent administration of some preparation of mercury in parasiticidal doses.

The abuse, therefore, of a potent remedy should not prejudice us against its proper use.

At one time there was a hue and cry against the use of mercury in the treatment of syphilis, and the non-mercurial cure was upheld by distinguished physicians. The reason, however, why they took up this anti-mercurial position was simply from their inability to discern between the use and abuse of the drug, or because popular prejudice was too strong for them; so that even when

they did prescribe it, they had to give it a false appellation. I believe, however, that now very few regular practitioners pretend to cure the disease without the aid of mercury, and, no doubt, the drug is more judiciously administered than in former times, when it was not an unusual occurrence with a patient to lose his teeth and hair.

It was the careless, not to say reckless, use of this drug that brought it into disrepute.

In proposing any new line of treatment, even when suggested by modern scientific research, we have always custom and prejudice to contend against.

Some months ago I was called in consultation to see a diphtheritic case, but was told by the attending physician that I need not propose the bichloride of mercury treatment, because he was opposed to it. Fortunately there was no call for discussing the matter, as the patient had reached that stage of the disease when iron and strychnine are the indications (to the exclusion of any preparation of mercury whatever) in the treatment.

Since then I treated successfully a very severe case of diphtheria in a boy eight years of age. The bichloride of mercury was given in what may be called the parasitic stage of the disease, and this was followed up by a course of iron and strychnine.

His sister, seven years of age, who had been sent to stay with another family, was allowed to come back to her home either too soon, or the incubative stage of the disease had not yet passed. At any rate, she was seized with the malady, and the father, in his excitement and disappointment, called in a doctor who scraped and swabbed the throat three or four times a day, while sprays and gargles were also in constant use; but, *post hoc* or *propter hoc*, the child died after two days of this treatment. On the other hand, the boy recovered, although his convalescence was tedious.

The last case worthy of notice is the one that has induced me to write this article in order to bring into the foreground the bichloride of mercury treatment in parasitical diseases, such as diphtheria, seeing that some physicians are yet a little diffident in using such a powerful drug.

In the forenoon of October 3d I was called to see a child, four years of age, who, to all appearance, was suffering from an advanced stage of diphtheria. The child was prostrate, the glands of the neck very much swollen, and an ichorous discharge was running from nose and eyes, and the breathing was somewhat impeded. The history of the case was very simple. The child had been ill four days, and had been treated by an Arab doctor, who declared to the parents that there was no disease of the throat, and that the swollen glands in the neck had nothing to do with any throat affection.

In the early morning of October 3d, however, he told the parents that there was something wrong with the throat.

The parents had suspected this before, and were now dissatisfied with the medical attendant and dismissed him.

It was at this juncture that I was called in, and, after taking a general survey of the child, I attempted to have a look at the throat, but the patient struggled severely against my endeavors. At last I succeeded, and found a large piece of membrane hanging loose in the throat, which came away on the handle of the spoon, along with some bloody mucus. There could be no doubt now as to the nature of the malady. I then examined the urine by heat and acid, and found that it was about one-half albumen. The case looked far from encouraging; still I had seen cases equally as bad recover under the bichloride of mercury treatment.

Two teaspoonfuls of castor-oil were administered at once, and the following mixture was ordered:

℞. Hydrargyri bichloridi .... gr. jss.
Glycerini ..... ʒ j.
Aquæ dest..... ..... ʒ iij.,

with the directions to give a teaspoonful (ʒ j.) to the patient every half hour till six doses were taken, and then to give it every hour, night and day.

An iodoform ointment (1 in 10) was also ordered to be rubbed over the swollen glands every three hours, and crude carbolic oil to be used for disinfecting the whole house. The diet prescribed was beef-tea, and milk with lime-water.

In the afternoon some of the members of the family called at my house to tell me that they wished to have a consultation, and that they had asked Drs. X—— and Y—— (European physicians) to meet me at 6.30 P.M.

When I went at the hour appointed I found Dr. Y—— already there, but Dr. X—— had sent a message to say that he could not come till half an hour later. Dr. Y—— and I therefore decided to conduct the consultation without Dr. X——, as I had another engagement at seven o'clock. After I had given the history of the case and a statement of the treatment adopted, Dr. Y—— examined the child, who resented furiously his throat being looked at. The symptoms were pretty much the same as they were in the morning, and there was not the slightest doubt in Dr. Y——'s mind but that this was a case of well-marked diphtheria; but he opened his eyes with amazement at my treatment, which, no doubt, he thought was simply a quasi-legal way of poisoning the patient.

His proposition was to give the child chlorate of potass and to swab the throat frequently with an antiseptic solution of carbolic acid, at the risk of driving the child into convulsions and of wasting its strength in struggling against this method of procedure.

My experience in the treatment of this disease had extended over a good many more years than that of my consultant, and I had to tell him that I had employed his treatment, and a good many others besides, with most unsatisfactory results; that I had no specific to offer, but that from what experience I had had during the last three years with the bichloride of mercury treatment in parasitic diseases in general, and in diphtheria and cholera in particular, I was satisfied that I had in my hands not merely a powerful poison, but an excellent curative agent.

He would have none of it, however, and persisted in trudging leisurely along the old hackneyed road, whose ruts were deep from age, and that no one thought of filling up, as the railway now ran alongside of it.

Well, we had just to agree to differ, and my treatment was continued, with the whole responsibility on my shoulders, and under the weight of the protest of my consultant.

October 4th, forenoon: Patient had taken the medicine regularly as ordered.

In the act of swallowing it, however, a small quantity was lost by running out at the nose. This happened to have a good effect on the nose, which was covered with diphtheritic membrane, and on observing this I had the nose syringed out from time to time with the bichloride solution.

The patient was decidedly brighter, but the albumen had increased in the urine more rapidly than I had ever observed in other cases that were being treated in the same way.

Seeing that the general condition of the patient was improved, notwithstanding the increased quantity of albumen in the urine, I reasoned with myself in this way: The raw absorptive surface left by the detached membrane, while favoring the entry of the bacteria directly into the circulation, also favored the absorption of their most potent destroyer, the bichloride; and, probably, the augmentation of albumen in the urine, with amelioration of the general condition of the patient, was simply an indication of the death and expulsion of bacteria. Treatment continued every hour.

October 4th, afternoon, six o'clock: Patient apparently about the same as in the morning, only there was a decided diminution in size of the swollen glands of the

neck. The urine, however, was nearly solid with albumen.

Notwithstanding that, I ordered the medicine to be given only once in two hours. The patient had now taken a little over one grain and a half of the bichloride.

October 5th, morning: Patient brighter; had a better night; medicine taken regularly; neck much less swollen, but still being rubbed every three hours with the iodoform ointment. What struck me most was the remarkable diminution in the quantity of albumen in the urine. It was only about one-twentieth of the volume, and never again increased during the whole treatment of the malady. The process of swallowing was still very imperfect, so that part of the medicine and nourishment escape by the nose. The fever, that was never very high, is now abating.

October 5th, evening: General improvement going on. Medicine ordered to be given every three hours, and a teaspoonful of vinum ferri between times.

The patient had now consumed fully two grains of the bichloride. This treatment was continued till October 9th, with gradual improvement of all the symptoms.

On October 9th I suspended the use of both the bichloride and the vinum ferri, and gave Fellow's syrup instead—half a teaspoonful (℥ ss.) every three hours.

On October 13th I left off attending the patient, giving instructions, however, to continue for some time with the Fellow's syrup. There was still a trace of albumen in the urine, and a little paralysis of the muscles of deglutition.

On October 17th the family physician, who had just returned from Europe, called to take me to see the child, as some new symptoms had developed. I found the child suffering from a little bronchial irritation, from having caught a cold. The urine was now perfectly free from albumen, and the only remains of the diphtheria was the slight paralysis of the throat that still continued. Fellow's solution was suspended for a day or two, while a stimulating expectorant was taken in its place.

On October 30th the child was brought to my surgery, comparatively well, but was ordered to continue his Fellow's syrup.

Remarks.—Mercury and its preparations are a parasiticide, and some of these preparations are more so than others.

The bichloride is, perhaps, the most potent, and is perfectly safe when intelligently used, and I should advise its being tried in all infectious or contagious diseases in preference to other preparations of mercury. Its well-known action in preserving the red globules of the blood intact is, no doubt, owing to its killing the bacteria that would otherwise cause their disintegration.

The biniodide is preferred by some physicians, and many who acknowledge the efficacy of other preparations of mercury still hesitate to employ the bichloride. As yet I have met with no untoward symptoms in using it; but should colic or irritation of the large bowel set in, then it ought to be suspended, at least for a time, and smaller doses given afterward.

In my last case of diphtheria, as recorded above, I am convinced that the natural detachment of the membrane favored the absorption of the drug, and thus also its curative action; and although I am averse to the forcible tearing away of the membrane, yet, without doubt, many bacteria are protected by it that we ought to endeavor to get at with as little annoyance to the patient as possible.

To effect this, it seems to me that the best method would be to employ some of the ingredients that are known to have a solvent effect upon the membrane, and these to be applied by means of spray, when the patient can neither gargle, nor drink, nor allow the throat to be touched.

We have all, no doubt, tried the effect of lime-water, as well as that of lactic acid, in this respect; but have we tried them with the addition of corrosive sublimate?

Of late "papayotin" has been in vogue in Germany as a remedy for diphtheria; but from the cases I have seen reported its action seems to me to be very decidedly solvent and nothing more. Still, that is a great matter when so many cases die of suffocation from the presence of the membrane.

Papayotin is prepared from the juice of the trunk and fruit of the South American melon-tree (*Carica papaya*).

It is innocuous when taken internally, but when injected into the blood it paralyzes the heart and nervous system.

It must not be used, therefore, without certain precautions. I should be very chary in applying it to a bleeding surface.

Its local application prevents the fibrinization of the serosity thrown out by the blood-vessels on any surface, whether on a mucous membrane or on an abraded skin, but the living, healthy mucous membrane is not affected by it.

Weak solutions of it have no solvent effect. About one to six is the average strength to be used, and may be applied to the part affected by converting it into spray by means of a brush, by gargling with it or by drinking it, and two or more of these methods may be combined if considered necessary or desirable, and persisted in every hour till the membrane is dissolved or obliterated, which will be the case, probably, after eight or even fewer applications.

In my opinion papayotin merely digests the membrane (just in the same way as the gastric juice digests the fibrinous material in our food), and may or may not have any parasiticidal action whatever. I have not the slightest doubt, however, that it forms an excellent adjuvant to the bichloride treatment of this formidable malady, that is still one of the *bêtes-noires* of the profession.

Syringing the nose with the antiseptic solution of the bichloride should not be neglected, as in this way the upper part of the pharynx comes under the direct influence of the remedy; while, if the false membrane has already been formed there, the papayotin may be applied to dissolve it away.

When the patient is not able to swallow, or refuses to take nourishment, and is very prostrate, I give enemas every four hours, consisting of about four ounces of strong beef-tea, with twenty drops of brandy. When milk can be taken, I prefer it to all other kinds of nourishment, and I generally add to it about one-third aqua calcis.

The following are the usual precautions I adopt in all diphtheritic cases:

First. Isolation of those who are not required to attend upon the patient.

Second. Thorough and constant disinfection of the whole house, but sick chamber and water-closets in particular.

For this purpose I use towels saturated with crude carbolic oil, and hang upon towel-racks or on any other suitable thing.

Third. Attendants are made to gargle their throats now and again with some disinfectant, or even with salt water.

Fourth. Chamber utensils are also disinfected.

I have also thought (although I have not as yet carried it into practice) that it would be a good precautionary measure to put both attendants and those who have been isolated on a mild bichloride régime as long as there was any danger of the appearance of the malady that might be still in its incubative stage.

I claim for the bichloride treatment this great advantage, that besides giving better results than other remedies the patient's strength is not wasted by those almost convulsive fits that are so frequently induced by the struggles of the patient to prevent the throat from being examined.

It is desirable that through the medium of your journal information should be given to the profession as to the experience of other medical men who may have already, or who will in the future, put this treatment still more extensively to the test.

Cairo, November 10, 1886.

Clinical Department.

DIGITAL AMPUTATIONS UNDER COCAINE.

Dr. Nelson L. North, Jr., of Brooklyn, N. Y., writes that he has used cocaine in a number of cases of finger amputations necessitated by various injuries, chiefly those caused by stamping-machines and circular saws. The operations varied in extent from the amputation of a part of the last phalanx to that of the greater part of an entire finger or thumb. The wound is first thoroughly saturated with a four per cent. solution of the hydrochlorate of cocaine before any examination is made; and then, after waiting a few minutes for absorption to take place, one can examine and probe the wound with entire satisfaction, as the patient makes no resistance, because he suffers no pain. Let us now proceed to cut our flaps, following each considerable incision with a few drops of the cocaine solution, and using it also occasionally to wet the entire denuded part, and apply ligatures and saw or clip the bone as necessity may demand. The wound is now ready to be closed, and after thoroughly irrigating it with an antiseptic solution and providing for proper drainage, sutures are applied and the wound dressed in accordance with the principles of antiseptic surgery. The method is simply one of soaking the wound with the cocaine solution. The cocaine is not injected, not that there is any objection to such a procedure, but simply because it is unnecessary, the anæsthesia being sufficient without the use of the hypodermatic needle. The question has been asked whether cocaine does not interfere with primary union. In the cases which have fallen under the observation of the writer, no bad effects resulted from this method, either on the constitution of the patient or the healing of the wound.

TREATMENT OF "LOCO" POISONING IN IDAHO TERRITORY.

Dr. T. E. Wilcox, U.S.A., of Washington, D. C., writes that the treatment employed by the cow-boys in Idaho for poisoning by the loco-weed consists in amputation of the tails of the animals affected. They claim that they seldom lose any stock when this treatment is instituted early enough. "The paralysis," the writer adds, "is probably due to congestion of the spinal cord; it affects the posterior members first. The pupils are contracted, as after the use of eserine. Oxytropis Lambertii, astragalus mollissimus, and possibly others of the leguminosæ, are charged with producing loco-poisoning. In Idaho the cow-boys call these plants 'larkspur,' although true larkspur is rarely found in their line of march and at that season of the year."

INSOLUBILITY OF CAPSULES IN AN INFLAMED STOMACH.

Dr. B. H. Boyd, of La Fayette, Ind., referring to a paragraph in a recent issue to the effect that gelatine capsules are not dissolved in a stomach which is inflamed and irritable, following excess in the use of spirits, reports his experience as follows: "August 10th, at 11 A.M., saw Mr. D——, aged twenty-seven, married, thin, pale, anæmic, tremulous, was an habitual drinker, and had been lately on a spree, but has taken no stimulants for three days. Says he had a chill yesterday afternoon, and a high fever during evening and night. Skin, moist and soft. Temperature, 100°; pulse, 80, but irregular and intermittent. Ordered bromide and acetate potass., to be used freely and continuously; a purgative, and quin. sul., grs. xx., to be given next morning in capsules. August 11th, 4 P.M.—temperature, 103°; pulse, 88; the purgative had acted, and the other medicines had been given as ordered. August 12th, 8 A.M.—temperature, 98°; pulse, 80, and irregular. Urine scanty, high-colored, and containing no albumen. Gave quin. sul., grs xxv., in capsules, and continued salts of potass. At 5 P.M. of the same day the temperature was 103°; pulse, 88. Quin. sul., 3 ss., to be given next morning early. August 13th—remission as before. Repeated quinine capsules. Fever returned in the evening as usual. Quinine capsules ordered to be given again on the morning of the 14th. August 14th, 4 P.M.—temperature, 103.5°; pulse, 86. On examining the stools I found two capsules undissolved, with contents intact. I then ordered quin. sul., 3 ss., *in powders*, to be given next morning in water. I saw patient at 4 P.M. of same day, found the temperature 99°; pulse, 80, of normal volume, and regular. After this the temperature was never observed above 100°, and patient convalesced fairly, considering his broken-down condition.

"Patient used no alcoholic beverages nor medicines during these observations, and his diet consisted of milk, meat soups, eggs, oysters, and toast."

EARLY DENTITION.

Dr. F. B. Morrill, of North Berwick, Me., referring to a case reported recently by Dr. Winsor, relates the following: "I attended Mrs. H——, aged twenty-two, primipara, in confinement February 3, 1884, and delivered her of a female child after a natural labor. The mother was anæmic and asthenic, had had poor appetite through most of her gestation, her diet being made up largely of fruits and oatmeal, yeast-bread, and some beefsteak. She got up from her labor very well with the aid of tonic treatment. She had no milk, and I put the child on a prepared food. When the child was six weeks old, the father, who was employed as an operative in a woollen-mill, invited me in to see his baby's tooth. I with surprise accepted the invitation, and found the left central lower incisor through the gum, and in a week the right central lower incisor was through. The other teeth appeared at the usual time. On May 10, 1885, I again attended Mrs. H—— in confinement, delivering her of a male child weighing eleven pounds. The labor was a complicated one. The mother's condition was rather better during this gestation than in the previous one, but her diet was about the same. This baby's teeth are following the normal course."

Dr. A. Brothers, of this city, referring to the same subject, writes as follows: "My case was that of a child three weeks old with a hare-lip, in which the intermaxillary bone protruded. I operated for the deformity, notched with bone-forceps the misplaced bone, and forced it back to its proper place. Five weeks later, therefore at the age of eight weeks, an incisor tooth had cut its way through the portion of bone referred to. The cause for this seemed to me to be the increased activity which was set up by the operation."

CAN DIPHTHERIA BE COMMUNICATED BY TOOTH-FORCEPS?

Dr. J. W. Collins, of Toronto, Ont., writes: "During the month of January, 1887, there appeared in Toronto a man calling himself the 'king of dentists.' He held free clinics for the extraction of teeth every evening for one week. At these 'extracting bees' he would call upon all who had aching or decayed teeth to come forward and receive gratis the benefit of his wonderful skill, and, it is needless to add, he had plenty of work. During the latter part of the week I saw seven cases of diphtheria, all developed within two days. In each case one or more teeth had been extracted by this itinerant dentist. No other cases of the disease had been known in the community, either in my practice or in that of any of my professional brethren. Is it probable that the disease was communicated by the instruments?"

Progress of Medical Science.

The Propagation of Cardiac Murmurs to the Epigastric Area.—In 1881 Professor Federici showed with what ease and how definitely the area of the stomach could be mapped out by ascertaining by means of auscultation with the stethoscope the extent to which the sounds of the heart are audible in the epigastrium. Over the stomach both sounds can be clearly heard; over the colon, only the second. By percussion it is frequently difficult to distinguish a stomach note from one given by a distended colon. The propagation of the cardiac sounds gives a ready and reliable means of differentiation. Auscultation of the epigastrium may also be used as a means of separating cardiac murmurs. It is sometimes not easy to distinguish between an aortic-diastolic murmur propagated to the apex and a post-diastolic or a pre-systolic murmur, both of which latter are produced at the mitral orifice. It is found, however, that murmurs produced at the aortic orifice are not propagated to the stomach area, whereas mitral murmurs are clearly audible over the stomach. Vanni has recently (*Lo Sperimentale*) confirmed these statements by clinical observations and post-mortem investigations.

Primary Cancer of Bronchial Glands and Lung.—At a recent meeting of the Academy of Medicine in Ireland (*The Dublin Journal of Medical Science*, November, 1886) Dr. M. A. Boyd read a paper on intra-thoracic cancer, which he described as being met with in two situations—the bronchial glands and anterior mediastinum. The former variety, when it involved the lung, was frequently in its advanced stages mistaken for phthisis, the latter for aneurism. He read the histories of three cases which came under his observation last year in the Mater Misericordiæ Hospital, with the post-mortem examinations made in each case. He regarded the symptoms described in standard works as indicating cancer—such as fixed pain in the chest, red-currant jelly expectoration, and enlargement of cervical glands—as unreliable, these symptoms not being present in a fourth of the recorded cases. He considered constant blood-spitting, with congestion of the larynx, and aphonia, with or without paralysis of vocal cords, and urgent dyspnœa, as more reliable signs; and as indicating the situation of the growth in the bronchial glands, with pressure on the bronchial veins and tubes. He considered the primary form of the disease as much more frequent in these situations than secondary formations when the disease began elsewhere. His general conclusions with regard to the disease were, that it occurred most frequently in hard drinkers; that pain was not a frequent symptom until pressure on the nerves in the thorax took place; that constant blood-spitting with symptoms of pressure on the bronchial tubes and obstruction in the œsophagus indicated malignant disease involving the bronchial glands; that, like malignant disease of the abdomen with effusion of blood-stained serum into the peritoneal cavity, malignant disease of the thorax was frequently accompanied by pleural effusion containing blood; that the disease sooner or later invaded the pericardium and compressed the superior vena cava, causing swelling of the face and upper extremity, and occasionally caused pressure on the recurrent laryngeal nerve, with paralysis of one or other vocal cord; that retro-sternal dulness, with displacement of the heart, and pressure on the vena cava, accompanied by paralysis of one or other vocal cord (aneurism being excluded) were absolutely diagnostic of mediastinal malignant disease; that malignant disease of the bronchial glands in its latter stages (when the patients most frequently sought advice), accompanied by muco-purulent expectoration mixed with blood, wasting, and night-sweats, resembled phthisis so closely that autopsies were not made, and the frequency of the disease in consequence was lost sight of. The disease in his experience was fatal in from two months to eight—his three cases having died about six months after the disease first showed itself.

The Efficacy of Basham's Mixture in Chronic Diffuse Nephritis.—Dr. A. L. Gihon reports (*The Chicago Medical Journal and Examiner*, January, 1887) a case of Bright's disease in which the albuminuria completely disappeared under the use of the mistura ferri et ammonii acetatis (U. S. Ph.). The patient was a naval officer, who developed nephritis after exposure to malarial influences during a long cruise on the China station. At the Naval Hospital, New York, where he was first received on reaching the United States, his urine was noted as "smoky, variable in quantity, containing from one-sixth to one-twelfth of its volume of albumen, with granular and hyaline casts. There was general œdema, with consequent dyspnœa, spasmodic breathing, interference with heart's action, and pains in the extremities." He improved sufficiently to permit his transfer to Washington, at his own request, that he might be with his family, but the fatigue of travel proved more than he was able to undergo, and he arrived in a state of extreme prostration, his heart acting feebly and tumultuously—beating one hundred and forty to one hundred and sixty per minute—pulse scarcely discoverable at the wrist, temperature ninety-nine, features pinched, eyes pearly, skin dull yellow, surface cold, clammy sweat, tongue broad, moist, pale and cold to the touch, great præcordial distress, dyspnœa, excessive restlessness, moaning, hiccough, distention over lower pleuræ, tumid abdomen, almost complete suppression of urine, and incessant violent retching and vomiting. He was put into a hot bath, dry cups applied over the loins, and the abdomen enveloped in hot turpentine stupes. Later the mistura ferri et ammonii acetatis, the use of which had been commenced at the Naval Hospital at New York, was administered in small doses alternately with boiled milk and lime-water, and repeated as often as it was vomited. This treatment, catharsis being at the same time established, was persisted in with such modifications as circumstances required. The irritability of the stomach gradually abated on the restoration of the secretion of urine. The Basham's mixture was continued in larger doses at longer intervals, and the symptoms continued to abate in severity. After a few months his urine was found to have a specific gravity of 1022, was slightly acid, and averaged daily thirty-four ounces; no casts and not the slightest trace of albumen were discoverable. Improvement became rapid. His flesh became firmer and of rosier color, all puffiness disappeared from the face, and all swelling from the lower extremities. Some abdominal distention remained. Of course the diffuse nephritis was not cured, but all untoward symptoms subsided for many months.

Paralysis Consequent on Parotitis.—Dr. Joffray has described a form of paralysis resulting from parotitis. It affected all four limbs, beginning, apparently, in the lower, and extending to the upper; the latter, however, being less markedly disturbed than the former. The paralysis was preceded by pains of a lancinating and constricting character, and became manifest about twenty-one days after the onset of the causal disease. It was associated with abolition of the reflexes—knee and plantar. The muscles failed to respond to faradic or galvanic excitation. This was the case not only with the muscles completely beyond volitional control, but also with those still capable of being influenced to some extent by the will of the patient. The sensibility of the muscles was increased, any slight pressure on them causing pain, while the sensibility of the skin itself seemed impaired. The special senses were intact. There was slight albuminuria, but no other disorder of the urinary function. Cure was effected, in the case of a child aged four and one-half years, in the course of four months, by the administration of iodide of potassium.—*Progrès Médical.*

THE MEDICAL RECORD:

SIMPLE CONSTIPATION AND ITS SUCCESSFUL MANAGEMENT.

AMONG the morbid states of the system for which suffering humanity seeks relief, often with but oftener without medical advice, none is probably of more frequent occurrence than constipation. From time immemorial to the present day countless expedients, including the use of innumerable drugs, have been resorted to in the endeavor to spur to renewed activity the flagging function of defecation. Sir Andrew Clarke has recently published some suggestive remarks concerning this subject, which, though not very original, nevertheless carry with them the weight of large experience and eminent practicality.

Sir Andrew inveighs particularly against the ignorant and unskilful domestic management of constipation, with its many untoward consequences, some of which may indeed become quite serious. He might with equal propriety have denounced the unskilful, because routine, practice of dealing with this disorder still practised by many medical men. The real mischief often begins by the self-conscious patient seeing imaginary evils impending from the accidental failure of his bowels to act on some occasion when he has decided that they ought to have done so. The *maladie imaginaire* forthwith concludes that the only way to relieve his "attack of constipation" is to take "a dose." And, he argues, the stronger the dose, the more effectual the cure. The medicine having operated, the bowels are probably found more inactive than before, which leads to renewed "doses." Soon the bowels fail to respond to natural stimuli, and periodical discharges are excited only by repeated doses of stronger and stronger aperients. In the words of Sir Andrew, "With few exceptions, no person has passed through this experience and fallen under the tyranny of aperients without finding his life invaded by a pack of petty nuisances which lower his health, vex his temper, and cripple his work."

Now, it is quite true that "for the most part all these troublesome consequences of constipation may be avoided by attending to the conditions of healthy defecation." Chief among these conditions are a sufficient quantity of digestible food—including plenty of liquid—the presence of enough refuse matters in the colon, a decent regard to nature's promptings, regular solicitation once every twenty-four hours, the co-operation of the will, and contentment with a moderate evacuation. Of course, this simple and natural regimen presupposes a healthy nervo-muscular apparatus, without which the function in question cannot be properly performed. Sir Andrew briefly discusses each of the above conditions; but they are so well known to the profession that it is unnecessary to dwell on any of them, except, perhaps, the last-named—*i.e.*, contentment with a moderate discharge. On that score there is probably more ignorance than on any other point connected with the subject. According to Clarke, "for a man of average weight, consuming an average amount of food, the average amount of fæces ready for discharge in twenty-four hours is about five ounces. This should be formed, sufficiently aërated to float, and coherent." There is not the slightest doubt that "many people expect to have a much more abundant discharge, and are dissatisfied or anxious if they do not get it." Such persons commonly resort to aperients in order to obtain "relief" from their imaginary constipation, and thus invite the very condition from which they are making misguided efforts to escape.

To effect a cure in such cases it is necessary, first of all, to stop aperients, and then to renew obedience to physiological laws. Sir Andrew's instructions to this large class of patients are so simple, direct, and practical that we cannot do better than here transcribe them:
